Executive Summary

Global climate change (GCC) is a change in the average weather of the earth that can be measured by wind patterns, storms, precipitation, and temperature. This paper is not a scientific analysis of the existence or potential causes of GCC. Further, this paper does not address National Environmental Policy Act (NEPA) requirements. Instead, the intent of this paper is to provide practical, interim information to California Environmental Quality Act (CEQA) practitioners to help Lead Agencies determine how to address GCC in CEQA documents prior to the development and adoption of guidance by appropriate government agencies.

A typical individual project does not generate enough greenhouse gas emissions to influence GCC significantly on its own; the issue of GCC is by definition a cumulative environmental impact. Therefore, if the Lead Agency chooses to address GCC effects in a CEQA document, it should be discussed in the context of a cumulative impact. A complicating factor, however, is that there are currently no published CEQA thresholds or approved methods for determining whether a project's potential contribution to a cumulative GCC impact is considerable.

This paper provides a summary of background information on GCC, the current regulatory environment surrounding greenhouse gas (GHG) emissions, and the various approaches that a Lead Agency may select in a CEQA document to address the potential impacts of GCC and a project's cumulative contribution to GHG. There are many potentially valid approaches, some of which may not be addressed in this paper; for this reason, this document does not recommend a single approach, but rather describes several alternative methodologies and factors that a Lead Agency can consider in selecting the most appropriate methodology for a particular project.

[1] Preparation of this paper was partially funded by Michael Brandman Associates

atmosphere regulates the earth's temperature. Without the natural heat trapping effect of GHG, the earth's surface would be about 34 degrees Centigrade (°C) cooler (CAT 2006). However, it is believed that emissions from human activities, such as electricity production and vehicle use, have elevated the concentration of these gases in the atmosphere beyond the level of naturally occurring concentrations.

Climate change is driven by forcings and feedbacks. A feedback is "an internal climate process that amplifies or dampens the climate response to a specific forcing" (NRC 2005). Radiative forcing is the difference between the incoming energy and outgoing energy in the climate system. The global warming potential (GWP) is the potential of a gas or aerosol to trap heat in the atmosphere; it is the "cumulative radiative forcing effects of a gas over a specified time horizon resulting from the emission of a unit mass of gas relative to a reference gas" (EPA 2006a).

Individual GHG species have varying GWP and atmospheric lifetimes. The carbon dioxide equivalent is a consistent methodology for comparing GHG emissions since it normalizes various GHG emissions to a consistent metric. The reference gas for GWP is carbon dioxide; carbon dioxide has a GWP of one. Compared to methane's GWP of 21, methane has a greater global warming effect than carbon dioxide on a molecule per molecule basis (EPA 2006b). One teragram (Tg) (equal to one million metric tons) of carbon dioxide equivalent (Tg CO_2 Eq.) is the mass emissions of an individual GHG multiplied by its GWP.

Of all greenhouse gases in the atmosphere, water vapor is the most abundant, important, and variable. It is not considered a pollutant; in the atmosphere, it maintains a climate necessary for life. The main source of water vapor is evaporation from the oceans (approximately 85 percent). Other sources include evaporation from other water bodies, sublimation (change from solid to gas) from ice and snow, and transpiration from plant leaves.

Ozone is a greenhouse gas; however, unlike other GHG, ozone in the troposphere is relatively short-lived and, therefore, is not global in nature. It is difficult to make an accurate determination of the contribution of ozone precursors (nitrogen oxides and volatile organic compounds) to GCC (CARB 2004b).

Aerosols are suspensions of particulate matter in a gas emitted into the air through burning biomass (plant material) and fossil fuels. Aerosols can warm the atmosphere by absorbing and emitting heat and can cool the atmosphere by reflecting light. Cloud formation can also be affected by aerosols. Sulfate aerosols are emitted when fuel containing sulfur is burned. Black carbon (or soot) is emitted during bio mass burning or incomplete combustion of fossil fuels. Particulate matter regulation has been lowering aerosol concentrations in the United States; however, global concentrations are likely increasing.

Carbon dioxide (CO_2) is an odorless, colorless gas, which has both natural and anthropogenic sources. Natural sources include the following: decomposition of dead organic matter; respiration of bacteria, plants, animals, and fungus; evaporation from oceans; and volcanic outgassing. Anthropogenic sources of carbon dioxide are from burning coal, oil, natural gas, and wood. Concentrations of carbon dioxide were 379 parts per million (ppm) in 2005, which is an increase of 1.4 ppm per year since 1960 (IPCC 2007).

Methane is a flammable gas and is the main component of natural gas. When one molecule of methane is burned in the presence of oxygen, one molecule of carbon dioxide and two molecules of water are released. There are no ill health effects from methane. A natural source of methane is from the anaerobic decay of organic matter. Geological deposits, known as natural gas fields, also contain methane, which is extracted for fuel. Other sources are from landfills, fermentation of manure, and cattle.

Nitrous oxide (N_2O), also known as laughing gas, is a colorless greenhouse gas. Higher concentrations can cause dizziness, euphoria, and sometimes slight hallucinations. Nitrous oxide is produced by microbial processes in soil and water, including those reactions that occur in fertilizer containing nitrogen. In addition to agricultural sources, some industrial processes (fossil fuel-fired power plants, nylon production, nitric acid production, and vehicle emissions) also contribute to its atmospheric load. It is used in rocket engines, racecars, and as an aerosol spray propellant.

Chlorofluorocarbons (CFCs) are gases formed synthetically by replacing all hydrogen atoms in methane or ethane with chlorine and/or fluorine atoms. CFCs are nontoxic, nonflammable, insoluble, and chemically unreactive in the troposphere (the level of air at the earth's surface). CFCs were first synthesized in 1928 for use as refrigerants, aerosol propellants, and cleaning solvents. They destroy stratospheric ozone; therefore, their production was stopped as required by the Montreal Protocol in 1987.

Hydrofluorocarbons (HFCs) are synthetic man-made chemicals that are used as a substitute for CFCs for automobile air conditioners and refrigerants.

Perfluorocarbons (PFCs) have stable molecular structures and do not break down though the chemical processes in the lower atmosphere. High-energy ultraviolet rays about 60 kilometers above the earth's surface are able to destroy the compounds. PFCs have very long lifetimes, between 10,000 and 50,000 years. Two common PFCs are tetrafluoromethane and hexafluoroethane. Concentrations of tetrafluoromethane in the atmosphere are over 70 parts per trillion (ppt) (EPA 2006d). The two main sources of PFCs are primary aluminum production and semiconductor manufacture.

Sulfur hexafluoride (SF_6) is an inorganic, odorless, colorless, nontoxic, nonflammable gas. It has the highest GWP of any gas evaluated, 23,900. Concentrations in the 1990s were about 4 ppt (EPA 2006d). Sulfur hexafluoride is used for insulation in electric power transmission and distribution equipment, in the magnesium industry, in semiconductor manufacturing, and as a tracer gas for leak detection.

International and Federal Legislation

International and Federal legislation has been enacted to deal with GCC issues. The Montreal Protocol was originally signed in 1987 and substantially amended in 1990 and 1992. The Montreal Protocol governs compounds that deplete ozone in the stratosphere—chlorofluorocarbons (CFCs), halons, carbon tetrachloride, and methyl chloroform. The Protocol provided that these compounds were to be phased out by 2000 (2005 for methyl chloroform).

In 1988, the United Nations and the World Meteorological Organization established the Intergovernmental Panel on Climate Change (IPCC) to assess "the scientific, technical and socio-economic information relevant to understanding the scientific basis of risk of human-induced climate change, its potential impacts, and options for adaptation and mitigation" (IPCC 2004).

c) Mid Mountain Facility: 150 DFU, 80 GPM
d) Development Total: 6,900 DFU, 1,650 GPM

2. In addition to the sewage flow demand created by the building development, parking drainage and pool backwash may also create additional sanitary sewer flow. These additional flows are assumed to be negligible compared to the rest of the project.

B. Sanitary Sewage Discharge

1. The daily sanitary sewer flow will be near the daily building cold water usage as detailed above.
   a) North Base**:** 44,700 GPD
   b) South Base: 22,000 GPD
   c) Mid Mountain Facility: 3,750 GPD
   d) Development Total: 70,400 GPD

IV. Gas

A. Demand Estimation:

1. Likely sources of gas consumption will be appliances, space heating, water heating, Pool heating, Ventilation air, and snowmelt. To predict the project gas demand we considered each one of these items separately for each of the resort areas. Appendix D summarizes each of the expected demands. Gas demand analysis assumed the following:
   a) Gas appliance quantities are as shown in Appendix A. Appliance consumption rates are as recommended by the 2001 CPC.
   b) Space peak heating gas consumption rate is 18 Btuh/sq.ft.
   c) Water peak heating gas consumption rate is 12 Btuh/sq.ft.
   d) Pool Heating gas consumption is based on uncovered, winter-time use.
   e) Snowmelt areas were assumed to be 6,000 sq.ft. prorated by square footage to various parts of the development. Energy input rate to snowmelt systems is assumed to be 200 Btuh/sq.ft.
   f) Appliance and Altitude Combustion efficiencies of 80%.
   g) 10% safety factor

2. Our results for gas demand are as follows:
   a) North Base – 83,400 MBH
   b) South Base – 83,000 MBH

c) Mid Mountain Facility – 3,300 MBH
d) Development Total – 154,000 MBH

B. Usage Estimation

1. In order to estimate annual consumption of gas a month by month analysis was completed for each gas use in each part of the development (Appendix E). In this analysis the following was used:
   a) Annual heating degree data from the state of California for the town of Tahoe City, CA to determine monthly gas consumption for space heating.
   b) Hours of appliance operation per month as shown in Appendix E.
   c) 50% of the daily water usage was assumed to be hot water.
   d) The mid-mountain building will not be operated during the summer months.

2. The Annual gas consumption is summarized here:
   a) North Base: 632,000 therms.
   b) South Base: 402,000 therms.
   c) Mid Mountain Facility: 30,500 therms.
   d) Development Total: 1,064,000 therms.

V. Electricity

A. Demand Estimation

1. Industry standard data for watts/sq.ft. were applied to each area on the project to calculate the expected electrical demand. Appendix F shows the load in each respective area of the project. Our study has estimated the following electrical demand for each building area on the project:
   a) North Base – 9.02 Megawatts(MW)
   b) South Base – 6.8 MW
   c) Mid-mountain – 250 kW
   d) Development total – 16 MW

2. Existing electrical demand data for the past two years was obtained from the utility company. The maximum site demand over the past couple of years was 1.6 MW. Most of this demand was due to ski lift operation. This 1.6 MW will still occur in addition to the building demands mentioned above.

B. Electrical Usage

1. Industry standard data for annual kWh/sq.ft. were applied to each area on the project to calculate the expected electrical demand. Appendix G shows the load in each respective area of the project. Our study has estimated the following electrical usage for each building area on the project:
   a) North Base – 14,417,000 kWh
   b) South Base – 6,528,000 kWh
   c) Mid-mountain – 741,000 kWh
   d) Development total – 43,374,000 kWh

2. Existing electrical usage data for the past two years was obtained from the utility company. The average annual resort energy usage was 1,220,000kWh. Again, we attribute most of this usage to ski lift operation. This usage will occur in addition to the building usages mentioned above.

C. On-site generation study

1. BGCE, Inc. completed an alternative energy study for micro-hydro turbine power systems on the mountain streams. We estimated the Madden and Ellis Creek systems could generate 589,000 kWh during three months of operation. This amount of power is estimated to be 1.4% of the developed resort's annual energy usage. This may seem trivial, but the annual power requirements of the eleven, 5,000 sq.ft. single family homes is estimated to be 856,000kWh. Therefore, just by operating three months a year, the Madden and Ellis systems could provide 68% of the annual electrical energy consumption for the eleven new homes.

2. Other potential uses of energy include, but are not limited to, the following:

   a) Homewood's renovation plan, by 2017, will have chairlifts requiring approximately 1,850 kW when running at full capacity. It is estimated that Homewood Mountain Resort demands 11,100 kWh per day to run all the chairlifts at full capacity. That being said, the proposed micro-hydro turbine generation systems could generate enough energy in a year to power all chairlifts at Homewood Mountain Resort for 53 days.

CEQA & Climate Change

Evaluating and Addressing Greenhouse Gas Emissions from Projects Subject to the California Environmental Quality Act

January 2008

"average" treatment plant. Thus, research will need to be conducted on a case-by-case basis to determine the "Fraction Anaerobically Digested" which is a function of the type of treatment process. Indirect emissions from these facilities can be calculated using the CCAR energy use protocols and URBEMIS model for transportation emissions.

Solid Waste Disposal Facilities

Air districts will have emission estimate methodologies established for methane emissions at permitted landfills. In addition, EPA's Landfill Gas Emissions Model (LandGem) and the CCAR methodology could also be used to quantify GHG emissions from landfill off gassing; however, this model requires substantial detail be input. The model uses a decomposition rate equation, where the rate of decay is dependent on the quantity of waste in place and the rate of change over time. This modeling tool is free to the public, but substantial project detail about the operation of the landfill is needed to run the model. Indirect emissions from these facilities can be calculated using the CCAR energy use protocols and URBEMIS model for transportation emissions.

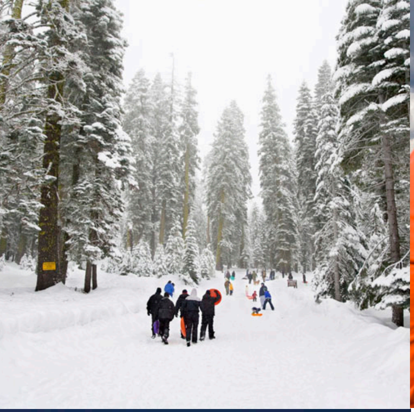
Construction Emissions

GHG emissions would occur during project construction, over a finite time. In addition, a project could result in the loss of GHG sequestration opportunity due primarily to the vegetation removed for construction. URBEMIS should be used to quantify the mass of CO_2 that would occur during the construction of a project for land development projects. Some construction projects would occur over an extended period (up to 20–30 years on a planning horizon for general plan buildout, or 5–10 years to construct a dam, for example). OFFROAD emission factors are contained in URBEMIS for CO_2 emissions from construction equipment. For other types of construction projects, such as roadway construction projects or levee improvement projects, SMAQMD's spreadsheet modeling tool, the Road Construction Emissions Model (RoadMod), should be used. This tool is currently being updated to include CO_2 emissions factors from OFFROAD.

The full life-cycle of GHG emissions from construction activities is not accounted for in the modeling tools available, and the information needed to characterize GHG emissions from manufacture, transport, and end-of-life of construction materials would be speculative at the CEQA analysis level. The emissions disclosed will be from construction equipment and worker commutes during the duration of construction activities. Thus, the mass emissions in units of metric tons CO_2e/year should be reported in the environmental document as new emissions.

General Plans

In the short-term, URBEMIS can be used as a calculation tool to model GHG emissions from proposed general plans, but only if data from the traffic study is incorporated into model input. The same methodology applied above in the specific plan example applies to general plans. The CCAR GRP can be used to approximate indirect emissions from



Climate Change Proposed Scoping Plan

APPENDICES

EXECUTIVE SUMMARY

On September 27, 2006, Governor Schwarzenegger signed Assembly Bill 32, the Global Warming Solutions Act of 2006 (Núñez, Chapter 488, Statutes of 2006). The event marked a watershed moment in California's history. By requiring in law a reduction of greenhouse gas (GHG) emissions to 1990 levels by 2020, California set the stage for its transition to a sustainable, clean energy future. This historic step also helped put climate change on the national agenda, and has spurred action by many other states.

The California Air Resources Board (ARB or Board) is the lead agency for implementing AB 32, which set the major milestones for establishing the program. ARB met the first milestones in 2007: developing a list of discrete early actions to begin reducing greenhouse gas emissions, assembling an inventory of historic emissions, establishing greenhouse gas emission reporting requirements, and setting the 2020 emissions limit.

ARB must develop a Scoping Plan outlining the State's strategy to achieve the 2020 greenhouse gas emissions limit. This Proposed Scoping Plan, developed by ARB in coordination with the Climate Action Team (CAT), proposes a comprehensive set of actions designed to reduce overall greenhouse gas emissions in California, improve our environment, reduce our dependence on oil, diversify our energy sources, save energy, create new jobs, and enhance public health. It will be presented to the Board for approval at its meeting in December 2008. The measures in the Scoping Plan approved by the Board will be developed over the next two years and be in place by 2012.

Reduction Goals

This plan calls for an ambitious but achievable reduction in California's carbon footprint. Reducing greenhouse gas emissions to 1990 levels means cutting approximately 30 percent from business-as-usual emission levels projected for 2020, or about 15 percent from today's levels. On a per-capita basis, that means reducing our annual emissions of 14 tons of carbon dioxide equivalent for every man, woman and child in California down to about 10 tons per person by 2020. This challenge also presents a magnificent opportunity to transform California's economy into one that runs on clean and sustainable technologies, so that all Californians are able to enjoy their rights in the future to clean air, clean water, and a healthy and safe environment.

Significant progress can be made toward the 2020 goal relying on existing technologies and improving the efficiency of energy use. A number of solutions are "off the shelf," and many – especially investments in energy conservation and efficiency – have proven economic benefits. Other solutions involve improving our state's infrastructure, transitioning to cleaner and more secure sources of energy, and adopting 21st century land use planning and development practices.

A Clean Energy Future

Getting to the 2020 goal is not the end of the State's effort. According to climate scientists, California and the rest of the developed world will have to cut emissions by 80 percent from today's levels to stabilize the amount of carbon dioxide in the atmosphere and prevent the most severe effects of global climate change. This long range goal is reflected in California Executive Order S-3-05 that requires an 80 percent reduction of greenhouse gases from 1990 levels by 2050.

Reducing our greenhouse gas emissions by 80 percent will require California to develop new technologies that dramatically reduce dependence on fossil fuels, and shift into a landscape of new ideas, clean energy, and green technology. The measures and approaches in this plan are designed to accelerate this necessary transition, promote the rapid development of a cleaner, low carbon economy, create vibrant livable communities, and improve the ways we travel and move goods throughout the state. This transition will require close coordination of California's climate change and energy policies, and represents a concerted and deliberate shift away from fossil fuels toward a more secure and sustainable future. This is the firm commitment that California is making to the world, to its children and to future generations.

Making the transition to a clean energy future brings with it great opportunities. With these opportunities, however, also come challenges. As the State moves ahead with the development and implementation of policies to spur this transition, it will be necessary to ensure that they are crafted to not just cut greenhouse gas emissions and move toward cleaner energy sources, but also to ensure that the economic and employment benefits that will accompany the transition are realized in California. This means that particular attention must be paid to fostering an economic environment that promotes and rewards California-based investment and development of new technologies and that adequate resources are devoted to building and maintaining a California-based workforce equipped to help make the transition.

A Public Process

Addressing climate change presents California with a challenge of unprecedented scale and scope. Success will require the support of Californians up and down the state. At every step of the way, we have endeavored to engage the public in the development of this plan and our efforts to turn the tide in the fight against global warming.

In preparing the Draft Scoping Plan, ARB and CAT subgroups held dozens of workshops, workgroups, and meetings on specific technical issues and policy measures. Since the release of the draft plan in late June, we have continued our extensive outreach with workshops and webcasts throughout the state. Hundreds of Californians showed up to share their thoughts about the draft plan, and gave us their suggestions for improving it. We've received thousands of postcards, form letters, emails, and over 1,000 unique comments posted to our website or sent by mail. All told, more than 42,000 people commented on the draft Plan.

ARB catalogued and publicly posted all the comments we received. In many instances, we engaged experts and staff at our partner agencies for additional evaluation of comments and suggestions.

This plan reflects the input of Californians at every level. Our partners at other State agencies, in the legislature, and at the local government level have provided key input. We've met with members of community groups to address environmental justice issues, with representatives of California's labor force to ensure that good jobs accompany our transition to a clean energy future, and with representatives of California's small businesses to ensure that this vital part of our state's economic engine flourishes under this plan. We've heeded the advice of public health and environmental experts throughout the state to design the plan so that it provides valuable co-benefits in addition to cutting greenhouse gases. We've also worked with representatives from many of California's leading businesses and industries to craft a plan that works in tandem with the State's efforts to continue strong economic growth.

In short, we've heard from virtually every sector of California's society and economy, reflecting the fact that the plan will touch the life of almost every Californian in some way.

Proposed Scoping Plan Recommendations

The recommendations in this plan were shaped by input and advice from ARB's partners on the Climate Action Team, as well as the Environmental Justice Advisory Committee (EJAC), the Economic and Technology Advancement Advisory Committee (ETAAC), and the Market Advisory Committee (MAC). Like the Draft Scoping Plan, the strength of this plan lies in the comprehensive array of emission reduction approaches and tools that it recommends.

Key elements of California's recommendations for reducing its greenhouse gas emissions to 1990 levels by 2020 include:

- **Expanding and strengthening existing energy efficiency programs as well as building and appliance standards;**
- **Achieving a statewide renewables energy mix of 33 percent;**
- **Developing a California cap-and-trade program that links with other Western Climate Initiative partner programs to create a regional market system;**
- **Establishing targets for transportation-related greenhouse gas emissions for regions throughout California, and pursuing policies and incentives to achieve those targets;**
- **Adopting and implementing measures pursuant to existing State laws and policies, including California's clean car standards, goods movement measures, and the Low Carbon Fuel Standard; and**

- **Creating targeted fees, including a public goods charge on water use, fees on high global warming potential gases, and a fee to fund the administrative costs of the State's long term commitment to AB 32 implementation.**

After Board approval of this plan, the measures in it will be developed and adopted through the normal rulemaking process, with public input.

Key Changes

This plan is built upon the same comprehensive approach to achieving reductions as the draft plan. However, as a result of the extensive public comment we received, this plan includes a number of general and measure-specific changes. The key changes and additions follow.

Additional Reports and Supplements

1. Economic and Public Health Evaluations: This plan incorporates an evaluation of the economic and public health benefits of the recommended measures. These analyses follow the same methodology used to evaluate the Draft Scoping Plan.[1]

2. CEQA Evaluation: This plan includes an evaluation of the potential environmental impacts of the Proposed Scoping Plan under the California Environmental Quality Act (CEQA).[2]

Programmatic Changes

1. Margin of Safety for Uncapped Sectors: The plan provides a 'margin of safety,' that is, additional reductions beyond those in the draft plan to account for measures in uncapped sectors that do not, or may not, achieve the estimated reduction of greenhouse gas emissions in this plan. Along with the certainty provided by the cap, this will ensure that the 2020 target is met.

2. Focus on Labor: The plan includes a discussion of issues directly related to California's labor interests and working families, including workforce development and career technical education. This additional element reflects ARB's existing activities and expanded efforts by State agencies, such as the Employment Development Department, to ensure that California will have a green technology workforce to address the challenges and opportunities presented by the transition to a clean energy future.

[1] Staff will provide an update to the Board to respond to comments received on these analyses.

[2] This evaluation is contained in Appendix J.

3. Long Term Trajectory: The plan includes an assessment of how well the recommended measures put California on the long-term reduction trajectory needed to do our part to stabilize the global climate.

4. Carbon Sequestration: The plan describes California's role in the West Coast Regional Carbon Sequestration Partnership (WESTCARB), a public-private collaboration to characterize regional carbon capture and sequestration opportunities. In addition, the plan expresses support for near-term development of sequestration technology. This plan also acknowledges the important role of terrestrial sequestration in our forests, rangelands, wetlands, and other land resources.

5. Cap-and-Trade Program: The plan provides additional detail on the proposed cap-and-trade program including a discussion regarding auction of allowances, a discussion of the proposed role for offsets, and additional detail on the mechanisms to be developed to encourage voluntary early action.

6. Implementation: The plan provides additional detail on implementation, tracking and enforcement of the recommended actions, including the important role of local air districts.

Changes to Specific Measures and Programs

1. Regional Targets: ARB re-evaluated the potential benefits from regional targets for transportation-related greenhouse gases in consultation with regional planning organizations and researchers at U.C. Berkeley. Based on this information, ARB increased the anticipated reduction of greenhouse gas emissions for Regional Transportation-Related Greenhouse Gas Targets from 2 to 5 million metric tons of CO_2 equivalent ($MMTCO_2E$).

2. Local Government Targets: In recognition of the critical role local governments will play in the successful implementation of AB 32, ARB added a section describing this role. In addition, ARB recommended a greenhouse gas reduction goal for local governments of 15 percent below today's levels by 2020 to ensure that their municipal and community-wide emissions match the State's reduction target.

3. Additional Industrial Source Measures: ARB added four additional measures to address emissions from industrial sources. These proposed measures would regulate fugitive emissions from oil and gas recovery and transmission activities, reduce refinery flaring, and require control of methane leaks at refineries. We anticipate that these measures will provide 1.5 $MMTCO_2E$ of greenhouse gas reductions.

4. Recycling and Waste Re-Assessment: In consultation with the California Integrated Waste Management Board, ARB re-assessed potential measures in the Recycling and Waste sector. As a result of this review, ARB increased the anticipated reduction of greenhouse gas emissions from the Recycling and Waste Sector from 1 to 10 $MMTCO_2E$, incorporating measures to move toward high recycling and zero-waste.[3]

5. Green Building Sector: This plan includes additional technical evaluations demonstrating that green building systems have the potential to reduce approximately 26 $MMTCO_2E$ of greenhouse gases. These tools will be helpful in reducing the carbon footprint for new and existing buildings. However, most of these greenhouse gas emissions reductions will already be counted in the Electricity, Commercial/Residential Energy, Water or Waste sectors and are not separately counted toward the AB 32 goal in this plan.

6. High Global Warming Potential (GWP) Mitigation Fee: Currently many of the chemicals with very high Global Warming Potential (GWP)—typically older refrigerants and constituents of some foam insulation products—are relatively inexpensive to purchase. ARB includes in this plan a Mitigation Fee measure to better reflect their impact on the climate. The fee is anticipated to promote the development of alternatives to these chemicals, and improve recycling and removal of these substances when older units containing them are dismantled.

7. Modified Vehicle Reductions: Based on current regulatory development, ARB modified the expected emissions reduction of greenhouse gases from the Heavy-Duty Vehicle Greenhouse Gas Emission Reduction (Aerodynamic Efficiency) measure and the Tire Inflation measure. The former measure is now expected to achieve 0.9 $MMTCO_2E$ while the latter is now expected to achieve 0.4 $MMTCO_2E$.

8. Discounting Low Carbon Fuel Standard Reductions: ARB modified the expected emission reductions from the Low Carbon Fuel Standard to reflect overlap in claimed benefits with California's clean car law (the Pavley greenhouse gas vehicle standards). This has the result of discounting expected reduction of greenhouse gas emissions from the Low Carbon Fuel Standard by approximately 10 percent.

A Balanced and Comprehensive Approach

Meeting the goals of AB 32 will require a coordinated set of strategies to reduce emissions throughout the economy. These strategies will fit within the comprehensive tracking,

[3] Research to help quantify these greenhouse gas emissions reductions is continuing, so only 1 $MMTCO_2E$ of these reductions are currently counted toward the AB 32 goal in this plan. Additional tons will be considered part of the safety margin.

reporting, and enforcement framework that is already being developed and implemented. By 2020, a hard and declining cap will cover 85 percent of California's greenhouse gas emissions, helping to ensure that we meet our reduction targets on time.

AB 32 lays out a number of important factors that have helped to guide the development of this plan and will continue to be considered as regulations are developed over the next few years. Some of the key criteria that have and will be further considered are: cost-effectiveness; overall societal benefits like energy diversification and public health improvements; minimization of leakage; and impacts on specific sectors like small business and disproportionately impacted communities. The comprehensive approach in the plan reflects a balance among these and other important factors and will help to ensure that California meets its greenhouse gas reduction targets in a way that promotes and rewards innovation, is consistent with and helps to foster economic growth, and delivers improvements to the environment and public health.

Many of the measures in this plan complement and reinforce one another. For instance, the Low Carbon Fuel Standard, which reduces the carbon intensity of transportation fuels sold in California, will work in tandem with technology-forcing regulations designed to reduce greenhouse gas emissions from cars and trucks. Improvements in land use and the ways we grow and build our communities will further reduce emissions from the transportation sector.

Many of the measures also build on highly successful long-standing practices in California—such as energy efficiency and the use of renewable energy resources—that can be accelerated and expanded. Increasing the amount of energy we get from renewable energy sources, including placing solar arrays and solar water heaters on houses throughout California, will be supported by an increase in building standards for energy efficiency. Other measures address the transport and treatment of water throughout the state, reduce greenhouse gas emissions that come from ships in California's ports, and promote changes to agricultural and forestry practices. There are also measures designed to safely reduce or recover a range of very potent greenhouse gases – refrigerants and other industrial gases – that contribute to global warming at a level many times greater per ton emitted than carbon dioxide.

Many of the measures in this plan are designed to take advantage of the economic and innovation-related benefits that market-based compliance strategies can provide. Particularly in light of current economic uncertainty, it is important to ensure that California's climate policies be designed to promote and take advantage of economic opportunities while also cutting greenhouse gas emissions. For instance, the cap-and-trade program creates an opportunity for firms to seek out cost-effective emission reduction strategies and provides an incentive for technological innovation. California's clean car standards, which require manufacturers to meet annual average levels of greenhouse gas emissions for all cars they sell in California, also offer flexibility to help ensure compliance. Under California's clean car standards, manufacturers who exceed compliance standards are permitted to bank credits for future use or sell them to other manufacturers. These types of compliance options will be key in ensuring that we are able to meet our reduction targets in a cost-effective manner.

Working with the Western Climate Initiative

California is working closely with six other states and four Canadian provinces in the Western Climate Initiative (WCI) to design a regional greenhouse gas emissions reduction program that includes a cap-and-trade approach. California's participation in WCI creates an opportunity to provide substantially greater reductions in greenhouse gas emissions from throughout the region than could be achieved by California alone. The larger scope of the program also expands the market for clean technologies and helps avoid leakage, that is, the shifting of emissions from sources within California to sources outside the state.

The WCI partners released the recommended design for a regional cap-and-trade program in September 2008.[4] ARB embraces the WCI effort, and will continue to work with WCI partners. The creation of a robust regional trading system can complement the other policies and measures included in this plan, and provide the means to achieve the reduction of greenhouse gas emissions needed from a wide range of sectors as cost-effectively as possible.

California's Economy, Environment, and Public Health

The approaches in this plan are designed to maximize the benefits that can accompany the transition to a clean energy economy. California has a long and successful track record of implementing environmental policies that also deliver economic benefits. This plan continues in that tradition.

AB 32: Evaluating the Economic Effects

The economic analysis of this plan indicates that implementation of the recommended strategies to address global warming will create jobs and save individual households money.[5] The analysis also indicates that measures in the plan will position California to move toward a more secure, sustainable future where we invest heavily in energy efficiency and clean technologies. The economic analysis indicates that implementation of that forward-looking approach also creates more jobs and saves individual households more money than if California stood by and pursued an unacceptable course of doing nothing at all to address our unbridled reliance on fossil fuels.

Specifically, analysis of the Proposed Scoping Plan indicates that projected economic benefits in 2020 compared to the business-as-usual scenario include:

- Increased economic production of $33 billion
- Increased overall gross state product of $7 billion
- Increased overall personal income by $16 billion
- Increased per capita income of $200

[4] Details of the WCI recommendation are provided in Appendix D.

[5] See Appendix G.

- Increased jobs by more than 100,000

Furthermore, the results of the economic analysis may underestimate the economic benefits of the plan since the models that were used do not account for savings that result from the flexibility provided under market-based programs.

AB 32: The Environmental and Public Health Costs of Inaction

A key factor that was not weighed in the overall economic analysis is the potential cost of doing nothing. When these costs are taken into account, the benefits associated with implementing a comprehensive plan to cut greenhouse gas emissions become even clearer. As a state, California is particularly vulnerable to the costs associated with unmitigated climate change.

A summary report from the California Climate Change Center notes that a warming California climate would generate more smoggy days by contributing to ozone formation while also fostering more large brush and forest fires. Continuing increases in global greenhouse gas emissions at business-as-usual rates would result, by late in the century, in California losing 90 percent of the Sierra snow pack, sea level rising by more than 20 inches, and a three to four times increase in heat wave days. These impacts will translate into real costs for California, including flood damage and flood control costs that could amount to several billion dollars in many regions such as the Central Valley, where urbanization and limited river channel capacity already exacerbate existing flood risks.[6] Water supply costs due to scarcity and increased operating costs would increase as much as $689 million per year by 2050.[7] ARB analysis shows that due to snow pack loss, California's snow sports sector would be reduced by $1.4 billion (2006 dollars) annually by 2050 and shed 14,500 jobs; many other sectors of California's economy would suffer as well.

Failing to address climate change also carries with it the risk of substantial public health costs, primarily as a result of rising temperatures. Sustained triple-digit heat waves increase the health risk for several segments of the population, especially the elderly. But higher average temperatures will also increase the interactions of smog-causing chemicals with sunlight and the atmosphere to produce higher volumes of toxic byproducts than would otherwise occur. In the 2006 report to the Governor from the California Climate Center, it was reported that global increases in temperature will lead to increased concentrations and emissions of harmful pollutants

---

[7] A Report from: California Climate Change Center. *Climate Warming and Water Supply Management in California*. Document No. CEC-500-2005-195-SF. March 2006. pp.13-14 http://www.energy.ca.gov/2005publications/CEC-500-2005-195/CEC-500-2005-195-SF.PDF (accessed October 12, 2008).

in California.[8] Some cities in California are disproportionately susceptible to temperature increases since they already have elevated pollution levels and are subject to the heat-island effect that reduces nighttime cooling, allowing heat to build up and magnify the creation of additional harmful pollution. Low-income communities are disproportionately impacted by climate change, lacking the resources to avoid or adapt to these impacts. For example, low-income residents are less likely to have access to air conditioning to prevent heat stroke and death in heat waves. For California, then, taking action with other regions and nations to help mitigate the impacts of climate change will help slow temperature rise. This in turn will likely result in fewer premature deaths from respiratory and heat-related causes, and many thousands fewer hospital visits and days of illness.

California cannot avert the impacts of global climate change by acting alone. We can, however, take a national and international leadership role in this effort by demonstrating that taking firm and reasoned steps to address global warming can actually help spur economic growth.

AB 32: Providing Savings for Households and Businesses

This plan builds upon California's thirty-year track record of pioneering energy efficiency programs. Many of the measures in the plan will deliver significant gains in energy efficiency throughout the economy. These gains, even after increases in per unit energy costs are taken into account, will help deliver annual savings of between $400 and $500 on average by 2020 for households, including low-income households.

Businesses, both large and small, will benefit too. By 2020, the efficiency measures in the plan will decrease overall energy expenditures for businesses even after taking into account projected rises in per unit energy costs. Since small businesses spend a greater proportional share of revenue on energy-related costs, they are likely to benefit the most. Furthermore, businesses throughout the state will benefit from the overall economic growth that is projected to accompany implementation of AB 32 between now and 2020.

Similar savings are projected in the transportation sector. By reducing greenhouse gas pollution from more efficient and alternatively-fueled cars and trucks under California's Clean Car law (the Pavley greenhouse gas standards), consumers save on operating costs through reduced fuel use. Although cars will be marginally more expensive, owners will be paid back with savings over the lifetime of the car, and the average new car buyer will have an extra $30 each month for other expenditures. Current estimates indicate that consumer savings in 2020 for California's existing clean car standards will be over $12 billion. These savings give Californians the ability to invest their dollars in other sectors of the state's economy.

AB 32: Driving Investment and Job Growth

Addressing climate change also provides a strong incentive for investment in California. Our leadership in environmental and energy efficiency policy has already helped attract a large and growing share of the nation's venture capital investment in green technologies. Since AB 32 was signed into law, venture capital investment in California has skyrocketed. In the second quarter of 2008 alone, California dominated world investment in clean technology venture capital, receiving $800 million of the global total of $2 billion.[9]

These investments in building a new clean tech sector also translate directly into job growth. A study by U.C. Berkeley's Energy and Resources Group and Goldman School of Public Policy found that investments in green technologies produce jobs at a higher rate than investments in comparable conventional technologies.[10] And the National Venture Capital Association estimates that each $100 million in venture capital funding helps create 2,700 jobs, $500 million in annual revenues for two decades and many indirect jobs.[11]

AB 32: Improving Public Health

The public health analysis conducted for this Plan indicates that cutting greenhouse gases will also provide a wide range of additional public health and environmental benefits. By 2020, the economic value alone of the additional air-quality related benefits is projected to be on the order of $2.2 billion. Our analysis indicates that implementing the Proposed Scoping Plan will result in a reduction of 15 tons per day of combustion-generated soot (PM 2.5) and 61 tons per day of oxides of nitrogen (precursors to smog). These reductions in harmful air pollution would provide the following estimated health benefits in 2020, above and beyond those projected to be achieved as a result of California's other existing public health protection and improvement efforts:

- An estimated 400 premature deaths statewide will be avoided
- Almost 11,000 incidences of asthma and lower respiratory symptoms will be avoided
- 67,000 work loss days will be avoided

In addition to the quantified health benefits, our analysis also indicates that implementation of the measures in the plan will deliver a range of other public health benefits. These include health benefits associated with local and regional transportation-related greenhouse gas targets that will facilitate greater use of alternative modes of transportation such as walking and bicycling. These types of moderate physical activities reduce many serious health risks including coronary heart disease, diabetes, hypertension and obesity.[12] Furthermore, as specific measures are developed, ARB and public health experts will work together to ensure that they are designed with an eye toward capturing a broad range of public health co-benefits.

The results of both the economic and public health analyses are clear: guiding California toward a clean energy future with reduced dependence on fossil fuels will grow our economy, improve public health, protect the environment and create a more secure future built on clean and sustainable technologies.

State Leadership

California is committed to once again lead and support a pioneering effort to protect the environment and improve public health while maintaining a vibrant economy. Every agency, department and division will bring climate change considerations into its policies, planning and analysis, building and expanding current efforts to green its fleet and buildings, and managing its water, natural resources, and infrastructure to reduce greenhouse gas emissions.

In all these efforts, California is exercising a leadership role in global action to address climate change. It is also exemplifying the essential role states play as the laboratories of innovation for the nation. As California has done in the past in addressing emissions that caused smog, the State will continue to develop innovative programs that benefit public health and improve our environment and quality of life.

Moving Beyond 2020

AB 32 requires a return to 1990 emission levels by 2020. The Proposed Scoping Plan is designed to achieve that goal. However, 2020 is by no means the end of California's journey to a clean energy future. In fact, that is when many of the strategies laid out in this plan will just be kicking into high gear.

Take, for example, the regional transportation-related greenhouse gas emissions targets. In order to achieve the deep cuts in greenhouse gas emissions we will need beyond 2020 it will be necessary to significantly change California's current land use and transportation planning policies. Although these changes will take time, getting started now will help put California on course to cut statewide greenhouse gas emissions by 80 percent in 2050 as called for by Governor Schwarzenegger.

[12] Appendix H contains a reference list of studies documenting the public health benefits of alternative transportation.

Similarly, measures like the cap-and-trade program, energy efficiency programs, the California clean car standards, and the renewables portfolio standard will all play central roles in helping California meet its 2020 reduction requirements. Yet, these strategies will also figure prominently in California's efforts beyond 2020. Some of these measures, like energy efficiency programs and the renewables portfolio standard, have already delivered greenhouse gas emissions reduction benefits that will expand over time. Others, like the cap-and-trade program, will put in place a foundation on which to build well into the future. All of these measures, and many others in the plan, will ensure that California meets its 2020 target and is positioned to continue its international role as leader in the fight against global warming to 2050 and beyond.

A Shared Challenge

Californians are already responding to the challenge of reducing greenhouse gas emissions. Over 120 California cities and counties have signed on to the U.S. Conference of Mayors Climate Protection Agreement[13] and many have established offices of climate change and are developing comprehensive plans to reduce their carbon footprint. Well over 300 companies, municipalities, organizations and corporations are members of the California Climate Action Registry, reporting their greenhouse gas emissions on an annual basis. Many other businesses and corporations are making climate change part of their fiscal and strategic planning. ARB encourages these initial efforts and has set in place a policy to support and encourage other voluntary early reductions.

Successful implementation of AB 32 will depend on a growing commitment by a majority of companies to include climate change as an integral part of their planning and operations. Individuals and households throughout the state will also have to take steps to consider climate change at home, at work and in their recreational activities. To support this effort, this plan includes a comprehensive statewide outreach program to provide businesses and individuals with the widest range of information so they can make informed decisions about reducing their carbon footprints.

Californians will not have to wait for decades to see the benefits of a low carbon economy. New homes can achieve a near zero-carbon footprint with better building techniques and existing technologies, such as solar arrays and solar water heaters. Many older homes can be retrofitted to use far less energy than at present. A new generation of vehicles, including plug-in hybrids, is poised to appear in dealers' showrooms, and the development of the infrastructure to support hydrogen fuel cell cars continues. Cities and new developments will be more walkable, public transport will improve, and high-speed rail will give travelers a new clean transportation option.

[13] Mayors Climate Protection Center. *List of Participating Mayors.* http://www.usmayors.org/climateprotection/list.asp (accessed October 12, 2008)

That world is just around the corner. What lies beyond is even more exciting. Where will California be in 2050? By harnessing the ingenuity and creativity of our society and sparking the imagination of the next generation of Californians, California will make the transition to a clean-energy, low-carbon society and become a healthier, cleaner and more sustainable place to live. This plan charts a course toward that future.

ARB invites comment and input from the broadest array of the public and stakeholders as we move forward over the next two years to develop the individual measures, and develop the policies that will move us toward sustainable clean energy and away from fossil fuels. Your participation will help craft the mechanisms and measures to make this plan a reality. This is California's plan and together, we need to make the necessary changes to address the greatest environmental challenge we face. As Governor Schwarzenegger stated when he signed AB 32 into law two years ago, "We owe our children and we owe our grandchildren. We simply must do everything in our power to fight global warming before it is too late."

I. INTRODUCTION: A Framework for Change

California strengthened its commitment to address climate change when Governor Schwarzenegger signed Assembly Bill 32 (AB 32), the Global Warming Solutions Act of 2006 (Núñez, Chapter 488, Statutes of 2006). This groundbreaking legislation represents a turning point for California and makes it clear that a business-as-usual approach toward greenhouse gas emissions is no longer acceptable. In light of the need for strong and immediate action to counter the growing threat of global warming, AB 32 sets forth an aggressive timetable for achieving results.

AB 32 embodies the idea that California can continue to grow and flourish while reducing its greenhouse gas emissions and continuing its long-standing efforts to achieve healthy air, and protect and enhance public health. Achieving these goals will involve every sector of the state's $1.7 trillion economy and touch the life of every Californian.

As the lead agency for implementing AB 32, the California Air Resources Board (ARB or the Board) released a Draft Scoping Plan in June 2008, which laid out a comprehensive statewide plan to reduce California's greenhouse gas emissions to 1990 levels by 2020. This Proposed Scoping Plan builds upon that draft. This plan sets forth a comprehensive reduction strategy that combines market-based regulatory approaches, other regulations, voluntary measures, fees, policies, and programs that will significantly reduce emissions of greenhouse gases and help make our state cleaner, more efficient and more secure.

The Board will consider this Proposed Scoping Plan for approval at its December 2008 meeting. Once approved by the Board, the Scoping Plan will provide specific direction for the State's greenhouse gas emissions reduction program. The recommended measures will be developed into regulations over the next two years, to go into effect by January 1, 2012. As specific measures in the plan are developed, we will update and adjust our regulatory proposals as necessary to ensure that they reflect any new information, additional analyses, new technologies or other factors that emerge during the process.

ARB has conducted a transparent, wide-ranging public process to develop the Proposed Scoping Plan, including numerous meetings, workshops, and seminars with stakeholders. Substantial input on the development of the Proposed Scoping Plan came from formal advisory committees, meetings with industrial and business groups, non-profit organizations and members of the public, as well as written comments on the Draft Scoping Plan. ARB will continue its outreach activities to seek ongoing public input and will encourage early and continued involvement in the implementation of the plan from all Californians.

A. Summary of Changes from the Draft Scoping Plan

On June 26, 2008, ARB released the Draft Scoping Plan and requested public comment and input, while continuing to analyze the measures and their impact on California. Since the Draft Scoping Plan release, ARB has received almost 1,000 unique written comments as well as hundreds of verbal comments at workshops and in meetings. Taking into account that some written comments were submitted by multiple individuals, all told more than 42,000 people have commented on the draft plan. ARB has also completed detailed economic and public health evaluations of its recommendations. This Proposed Scoping Plan reflects changes made to the draft plan as a result of the comments and input received and the additional analysis performed. The Proposed Plan does not incorporate modifications as a result of comments on the economic and public health supplements. ARB is evaluating those comments and will propose any necessary modifications to the Board.

The key changes between the Draft Scoping Plan and the Proposed Scoping Plan are summarized below. The Proposed Scoping Plan includes the following modifications:

1. General

- Incorporates economic and public health analyses of the Proposed Scoping Plan. These analyses show that the recommendations in the Proposed Scoping Plan will have a net positive impact on both the economy and public health. These analyses follow the same methodology used to evaluate the Draft Scoping Plan. ARB is continuing to consider comments on the methodology and assumptions used in these analyses. Staff will provide an update to the Board as needed to respond to comments received on these analyses.
- Provides a “margin of safety” by recommending additional greenhouse gas emissions reduction strategies to account for measures in uncapped sectors that do not achieve the greenhouse gas emissions reductions estimated in the Proposed Scoping Plan. Along with the certainty provided by the cap, this will ensure that the 2020 target is met.
- Expands the discussion of workforce development, education, and labor to more fully reflect existing activities and the role of other state agencies in ensuring an adequate green technology workforce.
- Assesses how well the recommended measures put California on the long-term reduction trajectory needed to do our part to stabilize the global climate.
- Describes California’s role in the West Coast Regional Carbon Sequestration Partnership (WESTCARB), a public-private collaboration to characterize regional carbon capture and sequestration opportunities, and expresses support for near-term advancement of the technology and monitoring of its development. Acknowledges the important role of terrestrial sequestration.
- Provides greater detail on the mechanisms to be developed to encourage voluntary early action.
- Provides additional detail on implementation, tracking and enforcement of the recommended actions, including the important role of local air districts.

- Evaluates the potential environmental impacts of the Proposed Scoping Plan under the California Environmental Quality Act (CEQA). This evaluation is contained in Appendix J.

2. Proposed Measures

- Provides greater detail on the proposed cap-and-trade program including more detail on the allocation and auction of allowances, and clarification of the proposed role of offsets.
- Re-evaluates the potential benefits from regional targets for transportation-related greenhouse gases in consultation with regional planning organizations and researchers at U.C. Berkeley. Based on this information, ARB increased the anticipated greenhouse gas emissions reductions for Regional Transportation-Related Greenhouse Gas Targets from 2 to 5 million metric tons of CO_2 equivalent ($MMTCO_2E$).
- In recognition of the importance of local governments in the successful implementation of AB 32, adds a section describing this role and recommends a greenhouse gas emissions reduction target for local government municipal and community-wide emissions of a 15 percent reduction from current levels by 2020 to parallel the State's target.
- Adds four measures to address emissions from industrial sources. These proposed measures would regulate fugitive emissions from oil and gas recovery and gas transmission activities, reduce refinery flaring, and remove the methane exemption for refineries. These proposed measures are anticipated to provide 1.5 $MMTCO_2E$ of greenhouse gas reductions in 2020.
- In consultation with the California Integrated Waste Management Board, re-assesses potential measures in the Recycling and Waste sector. As a result of this assessment, ARB increased the reduction of greenhouse gas emissions that can ultimately be anticipated from the Recycling and Waste Sector from 1 to 10 $MMTCO_2E$, recommending measures to move toward high recycling and zero-waste. Research to help quantify these greenhouse gas emissions is continuing, so only 1 $MMTCO_2E$ of these reductions is currently counted towards the AB 32 goal in this plan.
- Estimates the potential reduction of greenhouse gas emissions from the Green Building sector. Green building systems have the potential to reduce approximately 26 $MMTCO_2E$ of greenhouse gas emissions. Since most of these emissions reductions are counted in the Electricity, Commercial/Residential Energy, Water or Waste sectors, emission reductions in the Green Building sector are not separately counted toward the AB 32 goal.
- Adds a High Global Warming Potential (GWP) Mitigation Fee measure to ensure that the climate impact of these gases is reflected in their price to encourage reduced use and end-of-life losses, as well as the development of alternatives.
- Reduces the expected greenhouse gas emissions reduction from the Heavy-Duty Vehicle Greenhouse Gas Emissions Reduction (Aerodynamic Efficiency) measure and the Tire Inflation measure based on ongoing regulatory

development. The Heavy-Duty Vehicle Greenhouse Gas Emissions Reduction (Aerodynamic Efficiency) measure is now expected to achieve 0.9 $MMTCO_2E$ and the Tire Inflation measure is now expected to achieve 0.4 $MMTCO_2E$.

- Modifies the expected reduction of greenhouse gas emissions from the Low Carbon Fuel Standard to account for potential overlap of benefits with the Pavley greenhouse gas vehicle standards. ARB discounted the expected emission reductions from the Low Carbon Fuel Standard by 10 percent.
- After further evaluation, moves the Heavy-Duty Truck Efficiency measure to the Goods Movement measure. ARB expects that market dynamics will provide an inducement to improve heavy-duty truck efficiency, and reductions in greenhouse gases in the future. ARB would consider pursuing direct requirements to reduce greenhouse gases if truck efficiency does not improve in the future.

B. Background

1. Climate Change Policy in California

California first addressed climate change in 1988 with the passage of AB 4420 (Sher, Chapter 1506, Statutes of 1988). This bill directed the California Energy Commission (CEC) to study global warming impacts to the state and develop an inventory of greenhouse gas emissions sources. In 2000, SB 1771 (Sher, Chapter 1018, Statutes of 2000) established the California Climate Action Registry to allow companies, cities and government agencies to voluntarily record their greenhouse gas emissions in anticipation of a possible program that would allow them to be credited for early reductions.

In 2001, the United Nations' Intergovernmental Panel on Climate Change (IPCC) reported that "there is new and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities." The following year, AB 1493 (Pavley, Chapter 200, Statutes of 2002) was signed into law, requiring ARB to develop regulations to reduce greenhouse gas emissions from passenger vehicles, light-duty trucks and non-commercial vehicles sold in California.

Recognizing the value of regional partners in addressing climate change, the governors of California, Washington, and Oregon created the West Coast Global Warming Initiative in 2003 with provisions for the states to work together on climate change-related programs.

Two years later Governor Schwarzenegger signed Executive Order S-3-05, calling for the State to reduce greenhouse gas emissions to 1990 levels by 2020 and to reduce greenhouse gas emissions to 80 percent below 1990 levels by 2050. The 2020 goal was established to be an aggressive, but achievable, mid-term target, and the 2050 greenhouse gas emissions reduction goal represents the level scientists believe is necessary to reach levels that will stabilize climate.

In 2006, SB 1368 (Perata, Chapter 598, Statutes of 2006) created greenhouse gas performance standards for new long-term financial investments in base-load electricity generation serving California customers. This law is designed to help spur the transition toward cleaner energy in California by placing restrictions on the ability of utilities to build new carbon-intensive plants or enter into new contracts with high carbon sources of electricity. Expiration of existing utility long-term contracts with coal plants will reduce greenhouse gas emissions when such generation is replaced by lower greenhouse gas-emitting resources. These reductions will reduce the need for utilities to submit allowances to comply with the cap-and-trade program.

2. Assembly Bill 32: The Global Warming Solutions Act

In 2006, the Legislature passed and Governor Schwarzenegger signed AB 32, the Global Warming Solutions Act of 2006, which set the 2020 greenhouse gas emissions reduction goal into law. It directed ARB to begin developing discrete early actions to reduce greenhouse gases while also preparing a Scoping Plan to identify how best to reach the 2020 limit. The reduction measures to meet the 2020 target are to become operative by 2012.

AB 32 includes a number of specific requirements for ARB:

- *Identify the statewide level of greenhouse gas emissions in 1990 to serve as the emissions limit to be achieved by 2020 (Health and Safety Code (HSC) §38550).* In December 2007, the Board approved the 2020 emission limit of 427 million metric tons of carbon dioxide equivalent ($MMTCO_2E$) of greenhouse gases.
- *Adopt a regulation requiring the mandatory reporting of greenhouse gas emissions (HSC §38530).* In December 2007, the Board adopted a regulation requiring the largest industrial sources to report and verify their greenhouse gas emissions. The reporting regulation serves as a solid foundation to determine greenhouse gas emissions and track future changes in emission levels.
- *Identify and adopt regulations for Discrete Early Actions that could be enforceable on or before January 1, 2010 (HSC §38560.5).* The Board identified nine Discrete Early Action measures including potential regulations affecting landfills, motor vehicle fuels, refrigerants in cars, port operations and other sources in 2007. The Board has already approved two Discrete Early Action measures (ship electrification at ports and reduction of high GWP gases in consumer products). Regulatory development for the remaining measures is ongoing.
- *Ensure early voluntary reductions receive appropriate credit in the implementation of AB 32 (HSC §38562(b)(3)).* In February 2008, the Board approved a policy statement encouraging voluntary early actions and establishing a procedure for project proponents to submit quantification methods to be evaluated by ARB. ARB, along with California's local air districts and the California Climate Action Registry, is working to implement this program. Voluntary programs are discussed further in Chapter II and in Chapter IV.

- *Convene an Environmental Justice Advisory Committee (EJAC) to advise the Board in developing the Scoping Plan and any other pertinent matter in implementing AB 32 (HSC §38591).* The EJAC has met 12 times since early 2007, providing comments on the proposed Early Action measures and the development of the Scoping Plan, and submitted its comments and recommendations on the draft Scoping Plan in October 2008. ARB will continue to work with The EJAC as AB 32 is implemented.
- *Appoint an Economic and Technology Advancement Advisory Committee (ETAAC) to provide recommendations for technologies, research and greenhouse gas emission reduction measures (HSC §38591).* After a year-long public process, The ETAAC submitted a report of their recommendations to the Board in February 2008. The ETAAC also reviewed and provided comments on the Draft Scoping Plan.

3. Climate Action Team

In addition to establishing greenhouse gas emissions reduction targets for California, Executive Order S-3-05 established the Climate Action Team (CAT) for State agencies in 2005. Chaired by the Secretary of the California Environmental Protection Agency (CalEPA), the CAT has helped to direct State efforts on the reduction of greenhouse gas emissions and engage key State agencies including ARB. The Health and Human Services Agency, represented by the Department of Public Health, is the newest member of the CAT. Based on numerous public meetings and the review of thousands of submitted comments, the CAT released its first report in March 2006, identifying key carbon reduction recommendations for the Governor and Legislature.

Climate Action Team
California Environmental Protection Agency
Business, Transportation, and Housing Agency
Health and Human Services Agency
Resources Agency
State and Consumer Services Agency
Governor's Office of Planning and Research
Air Resources Board
California Energy Commission
California Public Utilities Commission
Department of Food and Agriculture
Department of Forestry and Fire Protection
Department of General Services
Department of Parks and Recreation
Department of Transportation
Department of Water Resources
Integrated Waste Management Board
State Water Resources Control Board

In April 2007, the CAT released a second report, "Proposed Early Actions to Mitigate Climate Change in California," which details numerous strategies that should be initiated prior to the 2012 deadline for other climate action regulations and efforts.

AB 32 recognizes the essential role of the CAT in coordinating overall climate policy. AB 32 does not affect the existing authority of other state agencies, and in addition to

ARB, many state agencies will be responsible for implementing the measures and strategies in this plan. The CAT is central to the success of AB 32, which requires an unprecedented level of cooperation and coordination across State government. The CAT provides the leadership for these efforts and helps ARB work closely with our state partners on the development and implementation of the strategies in the Proposed Scoping Plan.

There are currently 12 subgroups within the CAT – nine that address specific economic sectors, and three that were formed to analyze broad issues related to implementing a multi-sector approach to greenhouse gas emissions reduction efforts. The CAT sector-based subgroups include: Agriculture, Cement, Energy, Forest, Green Buildings, Land Use, Recycling and Waste Management, State Fleet, and Water-Energy. The members of these subgroups are drawn from departments that work with or regulate industries in the sector. ARB participated in each of the subgroups. All of the subgroups held public meetings and solicited public input, and many had multiple public workshops.

In March 2008, the subgroups collectively submitted more than 100 greenhouse gas emissions reduction measures to ARB for consideration in the Draft Scoping Plan. Many of those recommendations are reflected in this plan, and a number of them focus on reducing greenhouse gas emissions from energy production and use.

Through the Energy Subgroup the California Energy Commission (CEC) and the California Public Utilities Commission (CPUC) are conducting a joint proceeding to provide recommendations on how best to address electricity and natural gas in the implementation of AB 32, including evaluation of how the Electricity sector might best participate in a cap-and-trade program. The two Commissions forwarded interim recommendations to ARB in March 2008 that supported inclusion of the Electricity sector in a multi-sector cap-and-trade program, and measures to increase the penetration of energy efficiency programs in both buildings and appliances and to increase renewable energy sources. The two Commissions have developed a second proposed decision that was released in September 2008. This proposed decision provides more detailed recommendations that relate to the electricity and natural gas sectors. Because implementation of the Scoping Plan will require careful coordination with the State's energy policy, ARB will continue working closely with the two Commissions on this important area during the implementation of the recommendations in the Scoping Plan.

There are also three subgroups which are not sector-specific. The Economic Subgroup reviewed cost information associated with potential measures that were included in the 2006 CAT report with updates reflected in the report, "Updated Macroeconomic Analysis of Climate Strategies," in October 2007. This report provided an update of the macroeconomic analysis presented in the March 2006 CAT report to Governor Schwarzenegger and the Legislature. The Research Subgroup coordinates climate change research and identifies opportunities for collaboration, and is presently working on a report to the Governor. The State Operations Subgroup has been created to work with State agencies to create a statewide plan to reduce State government's greenhouse gas emissions by a minimum of 30 percent by 2020.

In the first quarter of 2009, the Climate Action Team will release a report on its activities outside of its involvement in the development of the Proposed Scoping Plan. The CAT report will focus on several cross-cutting topics with which members of the CAT have been involved since the publication of the 2006 CAT report. The topics to be covered include research on the physical and consequent economic impacts of climate change as well as climate change research coordination efforts among the CAT members. There will also be an update on the important climate change adaptation efforts led by the Resources Agency and a discussion of cross-cutting issues related to environmental justice concerns. The CAT report will be released in draft form and will be available for public review in December 2008.

4. Development of the Greenhouse Gas Emission Reduction Strategy

In developing the Proposed Scoping Plan, ARB considered the State's existing climate change policy initiatives and the Early Action measures identified by the Board. Several advisory groups were formed to assist ARB in developing the Proposed Scoping Plan, including the Environmental Justice Advisory Committee (EJAC), the Economic and Technology Advancement Committee (ETAAC), and the Market Advisory Committee (MAC).

The Environmental Justice Advisory Committee (HSC §38591(a) et seq) advises ARB on development of the Scoping Plan and any other pertinent matter in implementing AB 32. The Board appoints its members, based on nominations received from environmental justice organizations and community groups.

The Economic and Technology Advancement Advisory Committee (HSC §38591(d)) includes members who are appointed by the Board based on expertise in fields of business, technology research and development, climate change, and economics. The ETAAC advises ARB on activities that will facilitate investment in, and implementation of, technological research and development opportunities, funding opportunities, partnership development, technology transfer opportunities, and related areas that lead to reductions of greenhouse gas emissions.

Members of the Market Advisory Committee (created under Executive Order S-20-06) were appointed by the Secretary of CalEPA based on their expertise in economics and climate change. The MAC advised ARB on the design of a cap-and-trade program for reducing greenhouse gas emissions.

Along with input from the advisory groups, ARB received submittals to a public solicitation for ideas, and numerous comments during public workshops, workgroup meetings, community meetings, and meetings with stakeholder groups. ARB held numerous workshops on the Draft Scoping Plan and convened workgroup meetings focused on program design and economic analysis. ARB and other involved State agencies also held sector-specific technical workshops to look in greater detail at potential emissions reduction measures.

ARB also looked outward to examine programs at the regional, national and international levels. ARB met with and learned from experts from the European Union, the United Kingdom, Japan, Australia, the United Nations, the Regional Greenhouse Gas Initiative, the RECLAIM program, and the U.S. Environmental Protection Agency (U.S. EPA).

After the release of the Draft Scoping Plan, ARB conducted workshops and community meetings around the state to solicit public input. The Environmental Justice Advisory Committee and the Economic and Technology Advancement Advisory Committee held meetings to review and provide additional comments on the Draft Scoping Plan. In addition, ARB held meetings with numerous stakeholder groups to discuss specific greenhouse gas emissions reduction measures.

As described before, ARB has reviewed and considered both the written comments and the verbal comments received at the public workshops and meetings with stakeholders. This input, along with additional analysis, has ultimately shaped this Proposed Scoping Plan.

5. Implementation of the Scoping Plan

The foundation of the Proposed Scoping Plan's strategy is a set of measures that will cut greenhouse gas emissions by nearly 30 percent by the year 2020 as compared to business as usual and put California on a course for much deeper reductions in the long term. In addition to pursuing the reduction of greenhouse gas emissions, other strategies to mitigate climate change, such as carbon capture and storage (underground geologic storage of carbon dioxide), should also be further explored. And, as greenhouse gas reduction measures are implemented, we will continually evaluate how these measures can be optimized to also help deliver a broad range of public health benefits.

Most of the measures in this Proposed Scoping Plan will be implemented through the full rulemaking processes at ARB or other agencies. These processes will provide opportunity for public input as the measures are developed and analyzed in more detail. This additional analysis and public input will likely provide greater certainty about the estimates of costs and expected greenhouse gas emission reductions, as well as the design details that are described in this Proposed Scoping Plan. With the exception of Discrete Early Actions, which will be in place by January 1, 2010, other regulations are expected to be adopted by January 1, 2011 and take effect at the beginning of 2012.

Some of the measures in the plan may deliver more emission reductions than we expect; others less. It is also very likely that we will figure out new and better ways to cut greenhouse gas emissions as we move forward. New technologies will no doubt be developed, and new ideas and strategies will emerge. The Scoping Plan puts

California squarely on the path to a clean energy future but it also recognizes that adjustments will probably need to occur along the way and that as additional tools become available they will augment, and in some cases perhaps even replace, existing approaches.

California will not be implementing the measures in this Plan in a vacuum. Significant new action on climate policy is likely at the federal level and California and its partners in the Western Climate Initiative are working together to create a regional effort for achieving significant reductions of greenhouse gas emissions throughout the western United States and Canada. California is also developing a state Climate Adaptation Strategy to reduce California's vulnerability to known and projected climate change impacts.

ARB and other State agencies will continue to monitor, lead and participate in these broader activities. ARB will adjust the measures described here as necessary to ensure that California's program is designed to facilitate the development of integrated and cost-effective regional, national, and international greenhouse gas emissions reduction programs. (HSC §38564)

6. Climate Change in California

The impacts of climate change on California and its residents are occurring now. Of greater concern are the expected future impacts to the state's environment, public health and economy, justifying the need to sharply cut greenhouse gas emissions.

In the Findings and Declarations for AB 32, the Legislature found that:

> "The potential adverse impacts of global warming include the exacerbation of air quality problems, a reduction in quality and supply of water to the state from the Sierra snowpack, a rise in sea levels resulting in the displacement of thousands of coastal businesses and residences, damage to the marine ecosystems and the natural environment, and an increase in the incidences of infectious diseases, asthma, and other health-related problems."

The Legislature further found that global warming would cause detrimental effects to some of the state's largest industries, including agriculture, winemaking, tourism, skiing, commercial and recreational fishing, forestry, and the adequacy of electrical power.

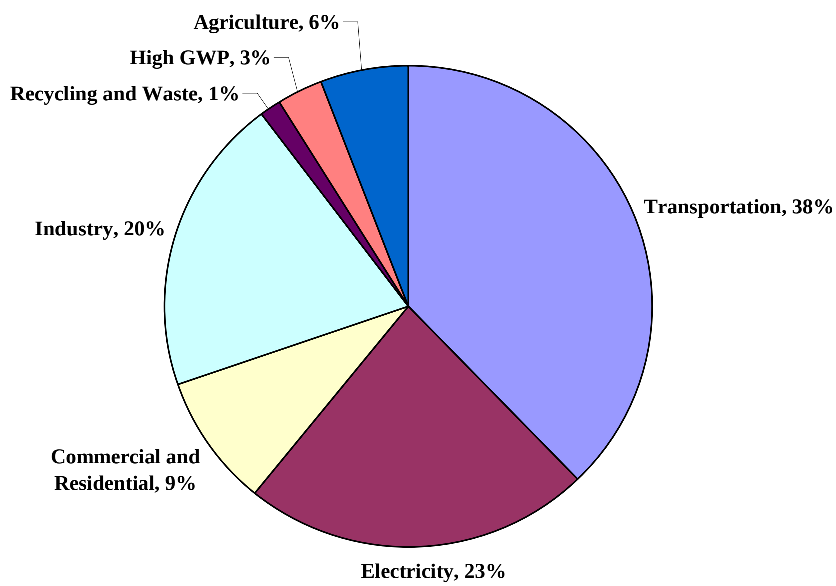
The impacts of global warming are already being felt in California. The Sierra snowpack, an important source of water supply for the state, has shrunk 10 percent in the last 100 years. It is expected to continue to decrease by as much as 25 percent by 2050. World-wide changes are causing sea levels to rise – about 8 inches of increase has been recorded at the Golden Gate Bridge over the past 100 years – threatening low coastal areas with inundation and serious damage from storms.

C. California's Greenhouse Gas Emissions and the 2020 Target

California is the fifteenth largest emitter of greenhouse gases on the planet, representing about two percent of the worldwide emissions. Although carbon dioxide is the largest contributor to climate change, AB 32 also references five other greenhouse gases: methane (CH_4), nitrous oxide (N_2O), sulfur hexafluoride (SF_6), hydrofluorocarbons (HFCs), and perfluorocarbons (PFCs). Many other gases contribute to climate change and would also be addressed by measures in this Proposed Scoping Plan.

Figure 1 and Table 1 show 2002 to 2004 average emissions and estimates for projected emissions in 2020 without any greenhouse gas reduction measures (business-as-usual case). The 2020 business-as-usual forecast does not take any credit for reductions from measures included in this Proposed Plan, including the Pavley greenhouse gas emissions standards for vehicles, full implementation of the Renewables Portfolio Standard beyond current levels of renewable energy, or the solar measures. Additional information about the assumptions in the 2020 forecast is provided in Appendix F.

Figure 1: California's Greenhouse Gas Emissions (2002-2004 Average)[14]



As seen in Figure 1, the Transportation sector – largely the cars and trucks that move goods and people – is the largest contributor with 38 percent of the state's total greenhouse gas emissions. Table 1 shows that if we take no action, greenhouse gas emissions in the

[14] Air Resources Board. Greenhouse Gas Inventory. http://www.arb.ca.gov/cc/inventory/inventory.htm (accessed October 12, 2008)

Transportation sector are expected to grow by approximately 25 percent by 2020 (an increase of 46 $MMTCO_2E$).

The Electricity and Commercial/Residential Energy sector is the next largest contributor with over 30 percent of the statewide greenhouse gas emissions. Although electricity imported into California accounts for only about a quarter of our electricity, imports contribute more than half of the greenhouse gas emissions from electricity because much of the imported electricity is generated at coal-fired power plants. AB 32 specifically requires ARB to address emissions from electricity sources both inside and outside of the state.

California's Industrial sector includes refineries, cement plants, oil and gas production, food processors, and other large industrial sources. This sector contributes almost 20 percent of California's greenhouse gas emissions, but the sector's emissions are not projected to grow significantly in the future. The sector termed recycling and waste management is a unique system, encompassing not just emissions from waste facilities but also the emissions associated with the production, distribution and disposal of products throughout the economy.

Although high global warming potential (GWP) gases are a small contributor to historic greenhouse gas emissions, levels of these gases are projected to increase sharply over the next several decades, making them a significant source by 2020.

The Forest sector is unique in that forests both emit greenhouse gases and uptake carbon dioxide (CO_2). While the current inventory shows forests as a sink of 4.7 $MMTCO_2E$, carbon sequestration has declined since 1990. For this reason, the 2020 projection assumes no net emissions from forests.

The agricultural greenhouse gas emissions shown are largely methane emissions from livestock, both from the animals and their waste. Emissions of greenhouse gases from fertilizer application are also important contributors from the Agricultural sector. ARB has begun a research program to better understand the variables affecting these emissions. Opportunities to sequester CO_2 in the Agricultural sector may also exist; however, additional research is needed to identify and quantify potential sequestration benefits.

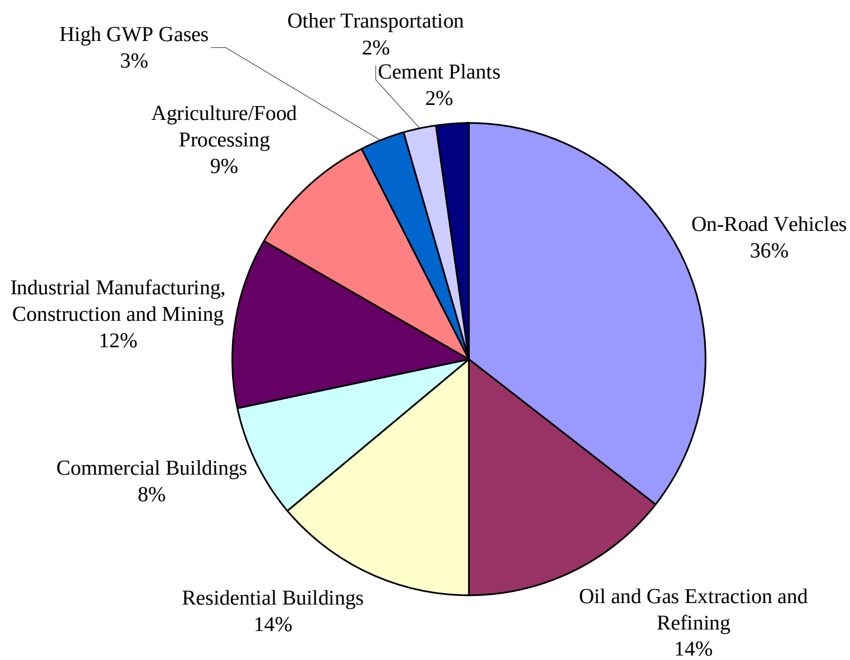
In December 2007, ARB approved a greenhouse gas emissions target for 2020 equivalent to the state's calculated greenhouse gas emissions level in 1990. ARB developed the 2020 target after extensive technical work and a series of stakeholder meetings. The 2020 target of 427 $MMTCO_2E$ requires the reduction of 169 $MMTCO_2E$, or approximately 30 percent, from the state's projected 2020 emissions of 596 $MMTCO_2E$ (business-as-usual) and the reduction of 42 $MMTCO_2E$, or almost 10 percent, from 2002-2004 average emissions.

Table 1: 2002-2004 Average Emissions and 2020 Projected Emissions (Business-as-Usual)[15]
(MMTCO$_2$E)

Sector	2002-2004 Average Emissions	Projected 2020 Emissions [BAU]
Transportation	179.3	225.4
Electricity	109.0	139.2
Commercial and Residential	41.0	46.7
Industry	95.9	100.5
Recycling and Waste	5.6	7.7
High GWP	14.8	46.9
Agriculture	27.7	29.8
Forest Net Emissions	-4.7	0.0
Emissions Total	**469**	**596**

Figure 2 presents California's historic greenhouse gas emissions in a different way – based not on the source of the emissions, but on the end use. This chart highlights the importance of addressing on-road transportation sources of greenhouse gas emissions, as well as the significant contribution from the heating, cooling, and lighting of buildings.

Figure 2: California's Greenhouse Gas Emissions – A Demand-Side View –



[15] Ibid.

The data shown in this section provide two ways to look at California's greenhouse gas profile – emissions-based and end use (demand side)-based. While it is possible to illustrate the inventory many different ways, no chart or graph can fully display how diverse economic sectors fit together. California's economy is a web of activity where seemingly independent sectors and subsectors operate interdependently and often synergistically. For example, reductions in water use reduce the need to pump water, directly lowering electricity use and associated greenhouse gas emissions. Similarly, reducing the generation of waste reduces the need to transport the waste to landfills – lowering transportation emissions and, possibly, landfill methane emissions. Increased recycling or re-use reduces the carbon emissions embedded in products – it takes less energy to make a soda can made from recycled aluminum than from virgin feedstock.

The measures included in this Proposed Scoping Plan are identified discretely, but many impact each other, and changes in one measure can directly overlap and have a ripple effect on the efficacy and success of other measures. The measures and policies outlined in this Plan reflect these interconnections, and highlight the need for all agencies to work collaboratively to implement the Scoping Plan.

II. RECOMMENDED ACTIONS

Achieving the goals of AB 32 in a cost-effective manner will require a wide range of approaches. Every part of California's economy needs to play a role in reducing greenhouse gas emissions. ARB's comprehensive greenhouse gas emissions inventory lists emission sources ranging from the largest refineries and power plants to small industrial processes and farm livestock. The recommended measures were developed to reduce greenhouse gas emissions from key sources and activities while improving public health, promoting a cleaner environment, preserving our natural resources, and ensuring that the impacts of the reductions are equitable and do not disproportionately impact low-income and minority communities. These measures also put the state on a path to meet the long-term 2050 goal of reducing California's greenhouse gas emissions to 80 percent below 1990 levels. This trajectory is consistent with the reductions that are needed globally to help stabilize the climate. While the scale of this effort is considerable, our experience with cultural and technological changes makes California well-equipped to handle this challenge.

ARB evaluated a comprehensive array of approaches and tools to achieve these emission reductions. Reducing greenhouse gas emissions from the wide variety of sources can best be accomplished though a cap-and-trade program along with a mix of complementary strategies that combine market-based regulatory approaches, other regulations, voluntary measures, fees, policies, and programs. ARB will monitor implementation of these measures to ensure that the State meets the 2020 limit on greenhouse gas emissions.

An overall limit on greenhouse gas emissions from most of the California economy – the "capped sectors" – will be established by the cap-and-trade program. (The basic elements of the cap-and-trade program are described later in this chapter.) Within the capped sectors, some of the reductions will be accomplished through direct regulations such as improved building efficiency standards and vehicle efficiency measures. Whatever additional reductions are needed to bring emissions within the cap are accomplished through price incentives posed by emissions allowance prices. Together, direct regulation and price incentives assure that emissions are brought down cost-effectively to the level of the overall cap. ARB also recommends specific measures for the remainder of the economy – the "uncapped sectors."

Key elements of California's recommendations for reducing its greenhouse gas emissions to 1990 levels by 2020 include:

- **Expanding and strengthening existing energy efficiency programs as well as building and appliance standards;**
- **Achieving a statewide renewables energy mix of 33 percent;**
- **Developing a California cap-and-trade program that links with other Western Climate Initiative partner programs to create a regional market system;**
- **Establishing targets for transportation-related greenhouse gas emissions for regions throughout California and pursuing policies and incentives to achieve those targets;**
- **Adopting and implementing measures pursuant to existing State laws and policies, including California's clean car standards, goods movement measures, and the Low Carbon Fuel Standard; and**
- **Creating targeted fees, including a public goods charge on water use, fees on high global warming potential gases, and a fee to fund the administrative costs of the State's long-term commitment to AB 32 implementation.**

The recommended greenhouse gas emissions reduction measures are listed in Table 2 and are summarized in Section C below. The total reduction for the recommended measures slightly exceeds the 169 $MMTCO_2E$ of reductions estimated in the Draft Scoping Plan. This is the net effect of adding several measures and adjusting the emission reduction estimates for some other measures. The 2020 emissions cap in the cap-and-trade program is preserved at the same level as in the Draft Scoping Plan (365 $MMTCO_2E$).

The measures listed in Table 2 lead to emissions reductions from sources within the capped sectors (146.7 $MMTOCO_2E$) and from sources or sectors not covered by cap-and-trade (27.3 $MMTCO_2E$). As mentioned, within the capped sectors the reductions derive both from direct regulation and from the incentives posed by allowance prices. Further discussion of how the cap-and-trade program and the complementary measures work together to achieve the overall target is provided below.

Table 2 also lists several other recommended measures which will contribute toward achieving the 2020 statewide goal, but whose reductions are not (for various reasons including the potential for double counting) additive with the other measures. Those measures and the basis for not including their reductions are further discussed in Section C.

Table 2: Recommended Greenhouse Gas Reduction Measures

Recommended Reduction Measures	Reductions Counted Towards 2020 Target ($MMTCO_2E$)	
ESTIMATED REDUCTIONS RESULTING FROM THE COMBINATION OF CAP-AND-TRADE PROGRAM AND COMPLEMENTARY MEASURES		**146.7**
California Light-Duty Vehicle Greenhouse Gas Standards • Implement Pavley standards • Develop Pavley II light-duty vehicle standards	31.7	
Energy Efficiency • Building/appliance efficiency, new programs, etc. • Increase CHP generation by 30,000 GWh • Solar Water Heating (AB 1470 goal)	26.3	
Renewables Portfolio Standard (33% by 2020)	21.3	
Low Carbon Fuel Standard	15	
Regional Transportation-Related GHG Targets[16]	5	
Vehicle Efficiency Measures	4.5	
Goods Movement • Ship Electrification at Ports • System-Wide Efficiency Improvements	3.7	
Million Solar Roofs	2.1	
Medium/Heavy Duty Vehicles • Heavy-Duty Vehicle Greenhouse Gas Emission Reduction (Aerodynamic Efficiency) • Medium- and Heavy-Duty Vehicle Hybridization	1.4	
High Speed Rail	1.0	
Industrial Measures (for sources covered under cap-and-trade program) • Refinery Measures • Energy Efficiency & Co-Benefits Audits	0.3	
Additional Reductions Necessary to Achieve the Cap	34.4	
ESTIMATED REDUCTIONS FROM UNCAPPED SOURCES/SECTORS		**27.3**
High Global Warming Potential Gas Measures	20.2	
Sustainable Forests	5.0	
Industrial Measures (for sources not covered under cap and trade program) • Oil and Gas Extraction and Transmission	1.1	
Recycling and Waste (landfill methane capture)	1.0	
TOTAL REDUCTIONS COUNTED TOWARDS 2020 TARGET		**174**

Other Recommended Measures	Estimated 2020 Reductions ($MMTCO_2E$)
State Government Operations	1-2
Local Government Operations	TBD
Green Buildings	26
Recycling and Waste (other measures)	9
Water Sector Measures	4.8
Methane Capture at Large Dairies	1.0

[16] This number represents an estimate of what may be achieved from local land use changes. It is not the SB 375 regional target. ARB will establish regional targets for each Metropolitan Planning Organization (MPO) region following the input of the Regional Targets Advisory Committee and a public consultation process with MPOs and other stakeholders per SB 375.

The development of a California cap-and-trade program that links with other Western Climate Initiative partner programs to create a regional market system is a central feature of the overall recommendation. This program will lead to prices on greenhouse gas emissions, prices that will spur reductions in greenhouse gas emissions throughout the California economy, through application of existing technologies and through the creation of new technological and organizational options. The rationale for combining a cap-and-trade program with complementary measures was outlined by the Market Advisory Committee, which noted the following in its recommendations to the ARB:

> Before setting out the key design elements of a cap-and-trade program it is important to explain how the proposed emissions trading approach relates to other policy measures. The following considerations seem especially relevant:
>
> - The emissions trading program puts a cap on the total emissions generated by facilities covered under the system. Because a certain number of emissions allowances are put in circulation in each compliance period, this approach provides a measure of certainty about the total quantity of emissions that will be released from entities covered under the program.
> - The market price of emissions allowances yields an enduring price signal for GHG emissions across the economy. This price signal provides incentives for the market to find new ways to reduce emissions.
> - By itself, a cap-and-trade program alone will not deliver the most efficient mitigation outcome for the state. There is a strong economic and public policy basis for other policies that can accompany an emissions trading system. [17]

The Economic and Technology Advancement Advisory Committee (ETAAC) also addressed the benefits associated with a combined policy of cap and trade and complementary measures.

> A declining cap can send the right price signals to shape the behavior of consumers when purchasing products and services. It would also shape business decisions on what products to manufacture and how to manufacture them. Establishing a price for carbon and other GHG emissions can efficiently tilt decision-making toward cleaner alternatives. This cap and trade approach (complemented by technology-forcing performance standards) avoids the danger of having government or other centralized decision-makers choose specific technologies, thereby limiting the flexibility to allow other options to emerge on a level playing field.

[17] Recommendations of the Market Advisory Committee to the California Air Resources Board. *Recommendations for Designing a Greenhouse Gas Cap-and-Trade System for California*. June 30, 2007. p. 19. http://www.climatechange.ca.gov/publications/market_advisory_committee/2007-06-29_MAC_FINAL_REPORT.PDF (accessed October 12, 2008)

> If markets were perfect, such a cap and trade system would bring enough new technologies into the market and stimulate the necessary industrial RD&D to solve the climate change challenge in a cost effective manner. As the Market Advisory Committee notes, however, placing a price on GHG emissions addresses only one of many market failures that impede solutions to climate change. Additional market barriers and co-benefits would not be addressed if a cap and trade system were the only state policy employed to implement AB 32. Complementary policies will be needed to spur innovation, overcome traditional market barriers (e.g., lack of information available to energy consumers, different incentives for landlords and tenants to conserve energy, different costs of investment financing between individuals, corporations and the state government, etc.) and address distributional impacts from possible higher prices for goods and services in a carbon-constrained world.[18]

The Environmental Justice Advisory Committee (EJAC) also supports an approach that includes a price on carbon along with complementary measures. Although the EJAC recommends that the carbon price be established through a carbon fee rather than through a cap-and-trade program, they recognize the importance of mutually supportive policies:

> California should establish a three-pronged approach for addressing greenhouse gases: (1) adopting standards and regulations; (2) providing incentives; and (3) putting a price on carbon via a carbon fee. The three pieces support one another and no single prong can work without equally robust support from the others.[19]

In keeping with the rationale outlined above, ARB finds that it is critically important to include complementary measures directed at emission sources that are included in the cap-and-trade program. These measures are designed to achieve cost-effective emissions reductions while accelerating the necessary transition to the low-carbon economy required to meet the 2050 target:

- The already adopted Light-Duty Vehicle Greenhouse Gas Standards are designed to accelerate the introduction of low-greenhouse gas emitting vehicles, reduce emissions and save consumers money at the pump.
- The Low Carbon Fuel Standard (LCFS) is a flexible performance standard designed to accelerate the availability and diversity of low-carbon fuels by taking into consideration the full life-cycle of greenhouse gas emissions. The LCFS will reduce emissions and make our economy more resilient to future petroleum price volatility.
- The Regional Transportation-Related Greenhouse Gas Targets provide incentives for channeling investment into integrated development patterns and transportation

February 14, 2008. pp. 1-4 http://www.arb.ca.gov/cc/etaac/ETAACFinalReport2-11-08.pdf (accessed October 12, 2008)

[19] Recommendations and Comments of the Environmental Justice Advisory Committee on the Implementation of the Global Warming Solutions Act of 2006 (AB32) on the Draft Scoping Plan. October 2008. p. 10. http://www.arb.ca.gov/cc/ejac/ejac_comments_final.pdf (accessed October 12, 2008)

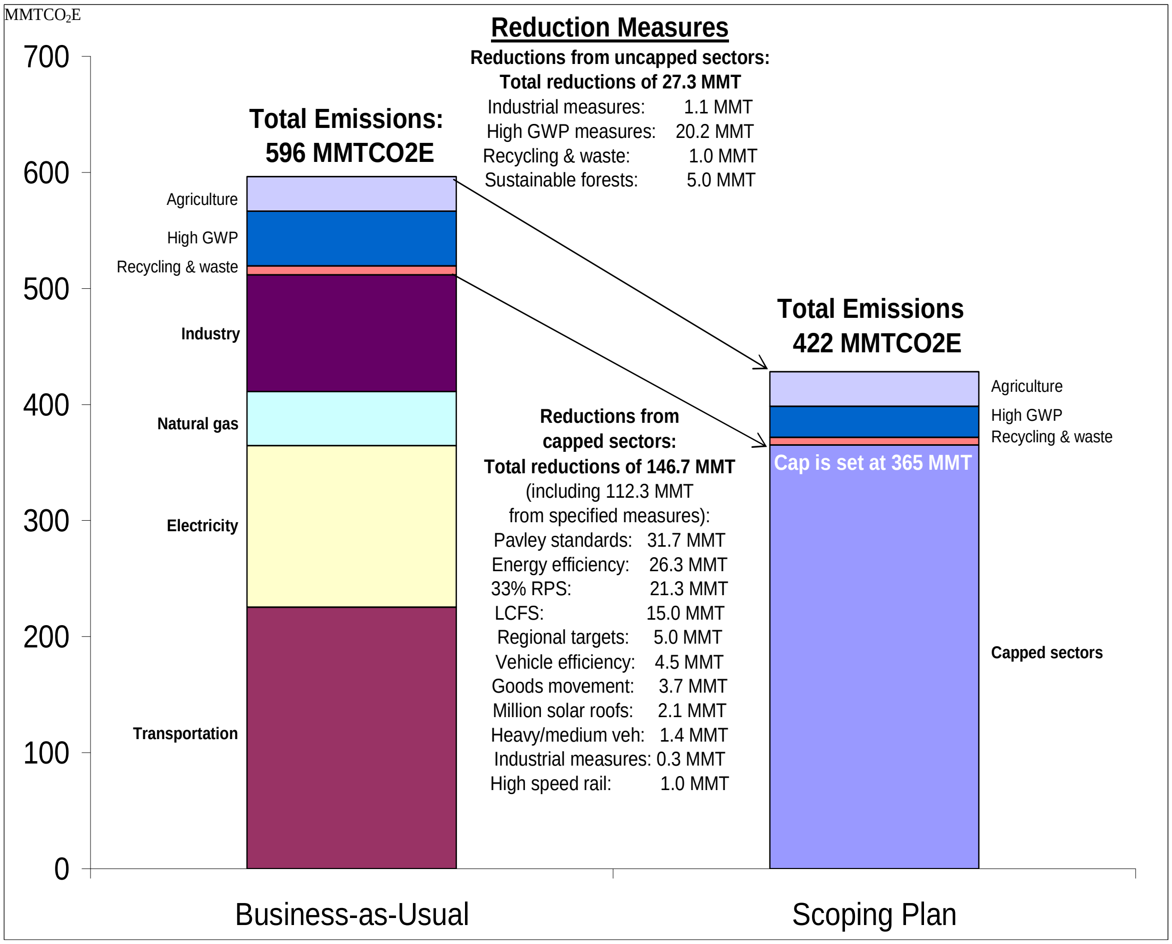
infrastructure, through improved planning. Improved planning and the resulting development are essential for meeting the 2050 emissions target.

- In the Energy sector, measures will provide better information and overcome institutional barriers that slow the adoption of cost-effective energy efficiency technologies. Enhanced energy efficiency programs will provide incentives for customers to purchase and install more efficient products and processes, and building and appliance standards will ensure that manufacturers and builders bring improved products to market.
- The Renewables Portfolio Standard (RPS) promotes multiple objectives, including diversifying the electricity supply. Increasing the RPS to 33 percent is designed to accelerate the transformation of the Electricity sector, including investment in the transmission infrastructure and system changes to allow integration of large quantities of intermittent wind and solar generation.
- The Million Solar Roofs Initiative uses incentives to transform the rooftop solar market by driving down costs over time.
- The Goods Movement program is primarily intended to achieve criteria and toxic air pollutant reductions but will provide important greenhouse gas benefits as well.
- Similar to the light duty vehicle greenhouse gas standards, the heavy duty and medium duty vehicle measures and the additional light duty vehicle efficiency measures aim to achieve cost-effective reductions of GHG emissions and save fuel.

Each of these complementary measures helps to position the California economy for the future by reducing the greenhouse gas intensity of products, processes, and activities. When combined with the absolute and declining emissions limit of the cap-and-trade program, these policies ensure that we cost-effectively achieve our greenhouse gas emissions goals and set ourselves on a path towards a clean low carbon future.

Figure 3 illustrates how the recommended emission reduction measures together put California on a path toward achieving the 2020 goal. The left hand column in Figure 3 shows total projected business as usual emissions in 2020, by sector (596 $MMTCO_2E$). The right hand column shows 2020 emissions after applying the Scoping Plan recommended reduction measures (422 $MMTCO_2E$). The measures that accomplish the needed reductions are listed in between the columns. As Figure 3 shows, there are a total of 27.3 $MMTCO_2E$ in reductions from uncapped sectors, and 146.7 $MMTCO_2E$ in reductions from capped sectors.

Figure 3: California Greenhouse Gas Emissions in 2020 and Recommended Reduction Measures



The recommended cap-and-trade program provides covered sources with the flexibility to pursue low cost reductions. It is important to recognize, however, that other recommended measures also provide compliance flexibility. As is often the case with ARB regulations, many of the measures establish performance standards and allow regulated entities to determine how best to achieve the required emission level. This approach rewards innovation and allows facilities to take advantage of the best way to meet the overarching environmental objective.

Table 3 lists the proposed measures that include compliance flexibility or market mechanisms. This flexibility ranges from the potential for tradable renewable energy credits in the Renewables Portfolio Standard to the incentives to encourage emission reductions in electricity and natural gas efficiency programs to the averaging, banking and trading mechanisms in the Pavley and Low Carbon Fuel Standard programs to a multi-sector cap-and-trade program.

Table 3: Measures With Flexible Market Compliance Features

Measure	Estimated Reductions
Additional Reductions from Capped Sectors	34.4
California Light-Duty Vehicle Greenhouse Gas Standards (Pavley I & II)	31.7
Renewables Portfolio Standard	21.3
Electricity Efficiency	15.2
Low Carbon Fuel Standard	15.0
Mitigation Fee on High GWP Gases	5.0
Natural Gas Efficiency	4.3
Goods Movement Systemwide Efficiency	3.5
Medium/Heavy Duty Vehicle Hybridization	0.5
Total	**130.9**

The recommended mix of measures builds on a strong foundation of previous action in California to address climate change and broader environmental issues. The program recommended here relies on implementing existing laws and regulations that were adopted to reduce greenhouse gas emissions and other policy goals; strengthening and expanding existing programs; implementing the discrete early actions adopted by the Board in 2007; and new measures developed during the Scoping Plan process itself.

The mix of measures recommended in this Proposed Plan provides a comprehensive approach to reduce emissions to achieve the 2020 target, and to initiate the transformations required to achieve the 2050 target. The cap-and-trade program and complementary measures will cover about 85 percent of greenhouse gas emissions throughout California's economy. ARB recognizes that due to several factors, including information discovered during regulatory development, technology maturity, and implementation challenges, actual reductions from individual measures aimed at achieving the 2020 target may be higher or lower than current estimates. The inclusion of many of these emissions within the cap-and-trade program, along with a margin of safety in the uncapped sectors, will help ensure that the 2020 target is met. The combination of approaches provides certainty that the overall program will meet the target despite some degree of uncertainty in the estimates for any individual measure. Additionally, by internalizing the cost of CO_2E emissions throughout the economy, the cap-and-trade program supports the complementary measures and provides further incentives for innovation and continuing emissions reductions from energy producers and consumers setting us on a path toward our 2050 goals.

Some emissions sources are not currently suitable for inclusion in the cap-and-trade program due to challenges associated with precise measurement, tracking or sector structure. For these emissions sources, ARB is including measures designed to focus on waste management, agriculture, forestry, and certain emissions of high GWP gases, a rapidly growing component of California's greenhouse gas emissions inventory.

California's economy is expected to continue to experience robust growth through 2020. Economic modeling, including evaluation of the effects on low-income Californians, shows that the measures included within this Proposed Scoping Plan can be implemented with a net positive effect on California's long-term economic growth. The evaluation of related public health and environmental benefits of the various measures also shows that implementation will result in not only reduced greenhouse gas emissions and improved public health, but also in a beneficial effect on California's environment. The results of these evaluations are presented in Chapter III.

AB 32 includes specific criteria that ARB must consider before adopting regulations for market-based compliance mechanisms to implement a greenhouse gas reduction program, and directs the Board, to the extent feasible, to design market-based compliance mechanisms to prevent any increase in the emissions of toxic air contaminants or criteria air pollutants. In the development of regulations that contain market mechanisms, ARB will consider the economic, environmental and public health effects, and the evaluation of potential localized impacts. These results will be used to institute appropriate economic, environmental and public health safeguards.

ARB has also designed the recommendation to ensure that reductions will come from throughout the California economy. Transportation accounts for the largest share of California's greenhouse gas emissions. Accordingly, a large share of the reduction of greenhouse gas emissions from the recommended measures comes from this sector. Measures include the inclusion of transportation fuels in the cap-and-trade program, the Low Carbon Fuel Standard to reduce the carbon intensity of transportation fuels, enforcement of regulations that reduce greenhouse gas emissions from vehicles, and policies to reduce transportation emissions by changes in future land use patterns and community design as well as improvements in public transportation.

In the Energy sector, the recommended measures increase the amount of electricity from renewable energy sources, and improve the energy efficiency of industries, homes and buildings. The inclusion of these sectors and the Industrial sector in the cap-and-trade program provides further assurance that significant cost-effective reductions will be achieved from the sectors that contribute the greatest emissions. Additional energy production from renewable resources may also rely on measures suggested in the Agriculture, Water, and the Recycling and Waste Management Sectors.

Other sectors are also called upon to cut emissions. The cap-and-trade program covers industrial sources and natural gas use. The recommended measures would require industrial processes to examine how to lower their greenhouse gas emissions and be more energy efficient, and would require goods movement operations through California's ports to be more energy efficient. Other measures address waste management, agricultural and forestry practices, as well as the transport and treatment of water throughout the state. Finally, the recommended measures address ways to reduce or eliminate the emissions of high global warming potential gases that, on a per-ton basis, contribute to global warming at a level many times greater than carbon dioxide.

As the Scoping Plan is implemented, ARB and other agencies will coordinate with the Green Chemistry Initiative, particularly in the Green Building and Recycling/Waste sectors. Green Chemistry is a fundamentally new approach to environmental protection that emphasizes environmental protection at the design stage of product and manufacturing processes, rather than focusing on end-of-pipe or end-of-life activities, or a single environmental medium, such as air, water or soil. This new approach will reduce the use of harmful chemicals, generate less waste, use less energy, and, accordingly, will contribute toward California's greenhouse gas reduction goals.

A. The Role of State Government: Setting an Example

For many years California State government has successfully incorporated environmental principles in managing its resources and running its business. The Governor has directed State agencies to sharply reduce their building-related energy use and encouraged our State-run pensions to invest in energy efficient and clean technologies.[20] The State also has been active in procuring low-emission, alternative fuel vehicles in its large fleet.

While State government has already accomplished much to reduce its greenhouse gas emissions, it can and must do more. State agencies must lead by example by continuing to reduce their greenhouse gas emissions. Therefore, California State government has established a target of reducing its greenhouse gas emissions by a *minimum* of 30 percent below its estimated business-as-usual emissions by 2020 – approximately a 15 percent reduction from current levels.

As an owner-operator of key infrastructure, State government has the ability to ensure that the most advanced, cost-effective environmental performance requirements are used in the design, construction, and operation of State facilities. As a purchaser with significant market power, State government has the ability to demand that the products and services it procures contribute positively toward California's targets to reduce greenhouse gas emissions, such as through the efforts of Environmentally Preferable Purchasing. As an investor of more than $400 billion,[21] State government has the ability to prioritize low-carbon investments. With more than 350,000 employees, State government is uniquely situated to adopt and implement policies that give State workers the ability to decrease their individual carbon impact, including encouraging siting facilities within communities to enhance balance in jobs and housing, encouraging carpooling, biking, walking, telecommuting, the use of public transit, and the use of alternative work schedules.

---

[20]Governor Schwarzenegger signed Executive Order Executive Order S-20-04 on December 14, 2004. This Order contains a number of directives, including a set of aggressive goals for reducing state building energy use and requested the California Public Employees Retirement System (CalPERS) and the California State Teachers Retirement System (CalSTRS) to target resource-efficient buildings for real estate investments and commit funds toward clean, efficient and sustainable technologies.

[21] CalPERS and CalSTRS are the two largest pension systems in the nation with investments in excess of $400 billion as of August 2008.

Myriad opportunities exist for California State government to operate more efficiently. These opportunities will not only reduce greenhouse gas emissions but also will produce savings for California taxpayers. Initiatives now underway that will contribute to the State government reduction target include the Governor's Green Building Initiative and the Department of General Services' efforts to increase the number of fuel-efficient vehicles in the State fleet.

Major efforts to expand renewable energy use and divest from coal-fired power plants are currently underway. Together with energy conservation and efficiency strategies on water projects, roadways, parks, and bridges, these efforts all play major roles in reducing the State's greenhouse gas emissions. State agencies should review their travel practices and make greater use of teleconferencing and videoconferencing to reduce the need for business travel, particularly air travel.

State agencies are now examining their policies and operations to determine how they can reduce their greenhouse gas emissions. These findings will be instrumental as each cabinet-level agency registers with the California Climate Action Registry (CCAR) to record and report their individual carbon footprints. The Climate Action Team has created a new State Government Operations sub-group that will work closely with the agencies to review the results of their evaluations and the CCAR reports to determine how best to achieve the maximum reductions possible.

State agencies must take the lead in driving this low-carbon economy by reducing their own emissions, and also by serving as a catalyst for local government and private sector activity. New "Best Practices" implemented by State agencies can be transferred to other entities within California, the nation, and internationally. By increasing cooperation and coordination across organizational boundaries, State government will maximize the experience and contributions of each agency involved to achieve the 30 percent reduction of greenhouse gas emissions while growing the economy and protecting the environment.

State government's impact on emissions goes far beyond its own buildings, vehicles, projects, and employees. State government casts a sizable "carbon shadow"– that is, the climate change impact of legislative, executive, and financial actions of State agencies that affect Californians now and in the future. For example, the California Energy Commission (CEC) recently initiated a proceeding to consider how to align its permitting process with the State's greenhouse gas and renewable energy policy goals. ARB intends to work closely with the CEC during this proceeding. New power plants, both fossil-fuel fired and renewable generation, will be a critical part of the state's electricity mix in coming decades. The investments that are made in this new infrastructure in the next several years will become part of the backbone of the state's electricity supply for decades to come. This timely investigation will be a critical element of California's ability to meet the AB 32 emissions reduction target for 2020, the ambitious target set by the Governor for 2050, and also the specific goal of achieving 33 percent renewables in the state's electricity mix. The Governor's Office of Planning and Research and the Resources Agency are developing proposed amendments to the California Environmental Quality Act (CEQA) Guidelines to provide guidance on how to address greenhouse gases in CEQA documents. As required by SB 97 (Chapter 185, Statutes of 2007), the amended CEQA guidelines will be adopted by January 1, 2010.

In addition, agencies such as the California Labor and Workforce Development Agency, the Business, Transportation and Housing Agency and the newly created Green Collar Jobs Council (AB 3018, Chapter 312, Statutes of 2008) are dedicated to economic development, training, safety, labor relations, and employment development throughout the State. ARB will coordinate with the Council and also with other State agencies to address workforce needs and facilitate a smooth transition to California's emerging low-carbon economy that maximizes economic development and employment opportunities in California.

The State expends funds to provide services to California residents – from preserving our natural resources to building and maintaining infrastructure like roads, bridges and dams. California residents should reap all of the benefits of these projects, including any associated quantifiable and marketable reductions in greenhouse gas emissions. Because of this, California should retain ownership of these greenhouse gas emissions reductions and use them to promote the goals of AB 32 and other goals of the state.

California State government can also lead through example by aligning its efforts to reduce greenhouse gas emissions with efforts to protect and improve public health. As a new member of the Climate Action Team, the Department of Public Health will help ensure that measures to combat global warming also incorporate public health protection and improvement strategies. As discussed below, these and many other State leadership efforts can be built upon at the local level as well.

B. The Role of Local Government: Essential Partners

Local governments are essential partners in achieving California's goals to reduce greenhouse gas emissions. They have broad influence and, in some cases, exclusive authority over activities that contribute to significant direct and indirect greenhouse gas emissions through their planning and permitting processes, local ordinances, outreach and education efforts, and municipal operations. Many of the proposed measures to reduce greenhouse gas emissions rely on local government actions.

Over 120 California cities have already signed on to the U.S. Conference of Mayors Climate Protection Agreement. In addition, over 30 California cities and counties have committed to developing and implementing Climate Action Plans. Many local governments and related organizations have already begun educating Californians on the benefits of energy efficiency measures, public transportation, solar homes, and recycling. These communities have not only demonstrated courageous leadership in taking initiative to reduce greenhouse gas emissions, they are also reaping important co-benefits, including local economic benefits, more sustainable communities, and improved quality of life.

Land use planning and urban growth decisions are also areas where successful implementation of the Scoping Plan relies on local government. Local governments have primary authority to plan, zone, approve, and permit how and where land is developed to accommodate population growth and the changing needs of their jurisdictions. Decisions on how land is used will have large impacts on the greenhouse gas emissions that will result from the transportation, housing, industry, forestry, water, agriculture, electricity, and natural gas sectors.

To provide local governments guidance on how to inventory and report greenhouse gas emissions from government buildings, facilities, vehicles, wastewater and potable water treatment facilities, landfill and composting facilities, and other government operations, ARB recently adopted the Local Government Operations Protocol. ARB encourages local governments to use this protocol to track their progress in achieving reductions from municipal operations. ARB is also developing an additional protocol for community emissions. This protocol will go beyond just municipal operations and include emissions from the community as a whole, including residential and commercial activity. These local protocols will play a key role in ensuring that strategies that are developed and implemented at the local level, like urban forestry and greening projects, water and energy efficiency projects, and others, can be appropriately quantified and credited toward California's efforts to reduce greenhouse gas emissions.

In addition to tracking emissions using these protocols, ARB encourages local governments to adopt a reduction goal for municipal operations emissions and move toward establishing similar goals for community emissions that parallel the State commitment to reduce greenhouse gas emissions by approximately 15 percent from current levels by 2020. To consolidate climate action resources and aid local governments in their emission reduction efforts, the ARB is developing various tools and guidance for use by local governments, including the next generation of best practices, case studies, a calculator to help calculate local greenhouse gas emissions, and other decision support tools.

The recent passage of SB 375 (Steinberg, Chapter 728, Statutes of 2008) creates a process whereby local governments and other stakeholders work together within their region to achieve reduction of greenhouse gas emissions through integrated development patterns, improved transportation planning, and other transportation measures and policies. The implementation of regional transportation-related greenhouse gas emissions targets and SB 375 are discussed in more detail in Section C.

C. Emissions Reduction Measures

The Scoping Plan will build on California's successful history of balancing effective regulations with economic progress. Several types of measures have been recommended. The plan includes a California cap-and-trade program that will be integrated with a broader regional market to maximize cost-effective opportunities to achieve GHG emissions reductions. The plan also includes transformational measures that are designed to help pave the path toward California's clean energy future. For example, the Low Carbon Fuel

Standard (LCFS) is a performance standard with flexible compliance mechanisms that will incent the development of a diverse set of clean, low-carbon transportation fuel options. Similarly, the plan recognizes the importance of local and regional government leadership in ensuring that California's land use and transportation planning processes are designed to be consistent with efforts to achieve a clean energy future and to protect and enhance public health and safety.

The Proposed Scoping Plan also contains a number of targeted measures that are designed to overcome existing barriers to action such as lack of information, lack of coordination, or other regulatory and institutional factors. Energy efficiency is a classic example where cost-effective action often is not taken due to lack of complete information, relatively high initial costs, and mismatches between who pays for and who benefits from efficiency investments. These problems often mean that efficiency measures are not taken that would save money in the long term for small businesses, home owners and renters. While California has a long history of success in implementing regulations and programs to encourage energy efficiency, innovative methods to overcome these economic and information barriers are needed to provide the benefits of increased efficiency to more Californians and to meet our greenhouse gas emissions reduction goals.

Several of the recommended measures complement each other. For example, the LCFS will provide clean transportation fuel options. The Pavley performance standards help deploy vehicles that can use many of the low-carbon fuels, including advanced biofuels, electricity and hydrogen. The combined operation of both programs will make it more likely that more efficient, less polluting vehicles will use the cleanest possible fuels. In addition, both of these programs will benefit from ARB's zero-emission vehicle program, which focuses on deployment of plug-in battery-electric and fuel cell vehicles. All of these strategies are expandable beyond 2020, and are needed as vital components to reach the State's 2050 goal.

The cap-and-trade program creates an emissions limit or "cap" on the sectors responsible for the vast majority of California's greenhouse gas emissions and provides capped sources significant flexibility in how they collectively achieve the reductions necessary to meet the cap. The other measures in these capped sectors provide a clear path toward achieving reductions required by the cap, while simultaneously addressing market barriers and creating the low-carbon energy options needed to achieve our long term climate goals. In the design of the cap-and-trade program, ARB will also evaluate possible ways to include features that complement the other measures, such as consideration of allowance set-asides that could be used to help achieve or exceed the aggressive energy efficiency goals included in this Plan.

Both required measures and other cost-effective actions by capped sectors will contribute toward achievement of the cap. For example, increasing energy efficiency will reduce electricity demand, thereby reducing the need for utilities to submit allowances to comply with the cap-and-trade program. In this way, energy efficiency contributes to real reductions toward the cap. Expiration of existing utility long-term contracts with coal plants will reduce GHG emissions when such generation is replaced by renewable generation, coal with carbon sequestration, or natural gas generation, which emits less CO_2 per megawatt-hour.

Additionally, measures and other actions that result in reductions in energy demand 'downstream' of capped sectors will help achieve the cap. For example, the Pavley vehicle standards, building efficiency standards, and land use planning that contributes to reduced transportation fuel demand will all reduce emissions by reducing the demand for upstream energy production. These downstream entities will further benefit from these reductions by avoiding any costs that would be passed through from a cap-and-trade system.

Discrete Early Actions

In September 2007, ARB approved a list of nine Discrete Early Actions to reduce greenhouse gas emissions and is currently in the process of developing regulations and programs based on these measures. Regulations implementing the Discrete Early Action measures must be adopted and in effect by January 1, 2010 (HSC §38560.5 (b)). All the Discrete Early Actions are included in the recommended measures and are shown below in Table 4.

Table 4: Anticipated Board Consideration Dates for Discrete Early Actions

Discrete Early Action	Anticipated Board Consideration
Green Ports – Ship Electrification at Ports	December 2007 – Adopted
Reduction of High GWP Gases in Consumer Products	June 2008 – Adopted
SmartWay – Heavy-Duty Vehicle Greenhouse Gas Emission Reduction (Aerodynamic Efficiency)	December 2008
Reduction of Perfluorocarbons from Semiconductor Manufacturing	February 2009
Improved Landfill Gas Capture	January 2009
Reduction of HFC-134a from Do-It-Yourself Motor Vehicle Servicing	January 2009
SF_6 Reductions from the Non-Electric Sector	January 2009
Tire Inflation Program	March 2009
Low Carbon Fuel Standard	March 2009

The following sections describe the recommended measures in this Proposed Scoping Plan. Additional information about these measures is provided in Appendix C.

1. California Cap-and-Trade Program Linked to Western Climate Initiative Partner Jurisdictions

Implement a broad-based California cap-and-trade program to provide a firm limit on emissions. Link the California cap–and-trade program with other Western Climate Initiative Partner programs to create a regional market system to achieve greater environmental and economic benefits for California. Ensure California's program meets all applicable AB 32 requirements for market-based mechanisms.

California is working closely with other states and provinces in the Western Climate Initiative (WCI) to design a regional cap-and-trade program that can deliver reductions of greenhouse gas emissions throughout the region. ARB will develop a cap-and-trade program for California that will link with the programs in the other WCI Partner jurisdictions to create a regional cap-and-trade program. The WCI Partner jurisdictions released the program design document on September 23, 2008 (see Appendix D). ARB will continue to work with the WCI Partner jurisdictions to develop and implement the cap-and-trade program. ARB will also design the California program to meet the requirements of AB 32, including the need to consider any potential localized impacts and ensure that reductions are enforceable by the Board.

Based on the requirements of AB 32, regulations to implement the cap-and-trade program need to be developed by January 1, 2011, with the program beginning in 2012. This rule development schedule will be coordinated with the WCI timeline for developing a regional cap-and-trade program. Preliminary plans for this rulemaking are described later in this section.

A cap-and-trade program sets the total amount of greenhouse gas emissions allowable for facilities under the cap and allows covered sources, including producers and consumers of energy, to determine the least expensive strategies to comply. The emissions allowed under the cap will be denominated in metric tons of CO_2E. The currency will be in the form of allowances which the State will issue based upon the total emissions allowed under the cap during any specific compliance period. Emission allowances can be banked for future use, encouraging early reductions and reducing market volatility. The ability to trade allows facilities to adjust to changing conditions and take advantage of reduction opportunities when those opportunities are less expensive than buying additional emissions allowances.

Provisions could be made to allow a limited use of surplus reductions of greenhouse gas emissions that occur outside of the cap. These additional reductions are known as offsets and are discussed further below. In order to be used to meet a source's compliance obligation, offsets will be subject to stringent criteria and verification procedures to ensure their enforceability and consistency with AB 32 requirements.

Appendix C describes the fundamentals of a cap-and-trade program and program design elements. Appendix D contains the WCI Design Recommendations and related background documents.

California Cap-and-Trade Program

By providing a firm cap on 85 percent of the state's greenhouse gas emissions, the cap-and-trade regulatory program is an essential component of the overall plan to meet the 2020 target and provides a robust mechanism to achieve the additional reductions needed by 2050. To meet the emissions reduction target under AB 32, the limit on emissions allowed under the cap, plus emissions from uncapped sources, must be no greater than the 2020 emissions goal.

By setting a limit on the quantity of greenhouse gases emitted, a well-designed cap-and-trade program will complement other measures for entities within covered sectors. Additionally, starting a cap-and-trade program now will set us on a course to achieve further emissions cuts well beyond 2020 and ensure that California is primed to take advantage of opportunities for linking with other programs, including future federal and international efforts.

The proposed cap-and-trade measure phases in the following sectors:

Starting in the first compliance period (2012):

- Electricity generation, including imports not covered by a WCI Partner jurisdiction
- Large industrial facilities that emit over 25,000 metric tons CO_2E per year.

Starting in the second compliance period (2015):

- Upstream treatment of industrial fuel combustion at facilities with emissions at or below 25,000 metric tons CO_2E, and all commercial and residential fuel combustion regulated where the fuel enters into commerce
- Transportation fuel combustion regulated where the fuel enters into commerce.

For some energy-intensive industrial sources such as cement, stringent requirements in California, either through inclusion in a cap-and-trade program or through source-specific regulation, have the potential to create a disadvantage for California facilities relative to out-of-state competitors unless those locations have similar requirements (e.g., through the WCI). If production shifts outside of California in order to operate without being subject to these requirements, emissions could remain unchanged or even increase. This is referred to as "leakage." AB 32 requires ARB to design measures to minimize leakage. Minimizing leakage will be a key consideration when developing the cap-and-trade regulation and the other AB 32 program measures.[22]

[22] The cement industry is an example of a sector that may be susceptible to this type of leakage, and the Draft Scoping Plan included consideration of a measure to institute an intensity standard at concrete batch plants that would consider this type of life-cycle emissions. ARB will evaluate whether this type of intensity standard could be incorporated into the cap-and-trade program or instituted as a complementary measure during the cap-and-trade rulemaking.

As shown in Table 5, the preliminary estimate of the cap on greenhouse gas emissions for sectors covered by the cap-and-trade program is 365 $MMTCO_2E$ in 2020, which covers about 85 percent of California's total greenhouse gas emissions.[23] Greenhouse gas emissions from most of the sectors covered by a cap-and-trade program will also be governed by other measures, including performance standards, efficiency programs, and direct regulations. These other measures will provide real reductions which will contribute reductions toward the cap.

In addition, ARB will work closely with the CPUC, CEC, and The California Independent System Operator to ensure that the cap-and-trade program works within the context of the State's energy policy and enables the reliable provision of electricity.

Table 5: Sector Responsibilities Under Cap-and-Trade Program ($MMTCO_2E$ in 2020)

Sector	Projected 2020 Business-as-Usual Emissions		Preliminary 2020 Emissions Limit under Cap-and-Trade Program
	By Sector	Total	
Transportation	225	512	365
Electricity	139		
Commercial and Residential	47		
Industry	101		

Linkage with the Western Climate Initiative Partner Jurisdictions

The WCI was formed in 2007. Members are California, Arizona, New Mexico, Oregon, Washington, Utah, and Montana, and the Canadian provinces of British Columbia, Manitoba, Ontario, and Quebec. The WCI Partner jurisdictions, including California, have adopted goals to reduce greenhouse gas emissions that, in total, reduce regional emissions to 15 percent below 2005 levels by 2020. This regional goal is approximately equal to California's goal of returning to 1990 levels by 2020. A cap-and-trade program is one element of the effort by the WCI Partner jurisdictions to identify, evaluate, and implement ways to reduce greenhouse gas emissions and achieve related co-benefits.

The WCI Partner jurisdictions released their recommendation for the design of a regional cap-and-trade program in September 2008. This design document and the

[23] The actual cap for the program will be established as part of the rulemaking process. The preliminary cap of 365 $MMTCO_2E$ in 2020 assumes that all of California's electricity imports would be covered under a California cap. Because a significant portion of California's imported electricity is from power plants located in other WCI Partner Jurisdictions, emissions from those sources could be included in the cap of the states within which the power plants are located. In establishing the California cap, ARB will need to consider the degree to which emissions from these sources are addressed as part of the WCI regional market.

background paper that accompanied it are presented in Appendix D. These recommendations were developed collaboratively by the WCI Partner jurisdictions, including California, with a goal of achieving regional targets to reduce greenhouse gas emissions equitably and effectively. The WCI Partner jurisdictions' recommendations are generally consistent with the recommendations provided in June 2007 by the California Market Advisory Committee,[24] the recommendations provided to ARB by the California Public Utilities Commission and the California Energy Commission in March 2008,[25] and the proposed opinion released by the two Commissions in September 2008.[26]

Participating in a regional system has several advantages for California. The reduction of greenhouse gas emissions that can be achieved collectively by the WCI Partner jurisdictions are approximately double what can be achieved through a California-only program. The broad scope of a WCI-wide market will provide additional opportunities for reduction of emissions, therefore providing greater market liquidity and more stable carbon prices within the program. The regional system also significantly reduces the potential for leakage, which is a shift in economic and emissions activity out of California that could hurt the state's economy without reducing global greenhouse gas emissions. Harmonizing the approach and timing of California's requirements for reducing greenhouse gas emissions with other states and provinces in the region can encourage retention of local businesses in the state. Further, by creating a cost-effective regional market system, California and the other WCI Partner jurisdictions will continue to demonstrate leadership in preparation for future federal and international climate action.

To achieve the individual WCI Partner jurisdiction goals and the regional goal, each WCI Partner jurisdiction will have an allowance budget based on its goal that declines to 2020. For example, California's allowance budget will be based on the level of emissions needed to achieve the AB 32 target for 2020, as described above. Once California links with the other WCI Partner jurisdictions, allowances could be traded across state and provincial boundaries. As a result of trading, emissions in a

state may vary from its allowance budget, although total regional emissions will not exceed the regional cap.

The overall number of allowances issued in a given year by the WCI Partner jurisdictions will set a limit on emissions from sectors covered by the program for the region. Details of distribution of allowances will be established by each partner within the general guidelines set forth in the WCI program design framework. The WCI Partner jurisdictions have agreed to consider standardizing allowance distribution across specific sectors if necessary to address competitiveness issues. In addition, the WCI Partner jurisdictions have agreed to phase in regionally coordinated auctions of allowances, with a minimum percentage of allowances auctioned in each period starting with 10 percent in the first compliance period and increasing to 25 percent in 2020. WCI partners aspire to reach higher auction percentages over time, possibly to 100 percent. Under the program design, each WCI Partner jurisdiction, including California, can auction a greater portion of its allowance budget in any compliance period. The distribution of California's allowances will be determined during the cap-and-trade rulemaking process, as discussed below.

The WCI Partner jurisdictions are also proposing the use of an allowance reserve price for the first 5 percent of the auctioned allowances in the regional cap. A reserve price will help to ensure that the cap is set at a level that will motivate real emissions reductions and may provide an opportunity for the regional cap-and-trade program to provide reductions that exceed the regional target.

A regional coordinated cap-and-trade program with strong reporting and enforcement rules will provide a high degree of certainty that emissions will not exceed targeted levels and that leakage will not occur.

Federal Action

A cap-and-trade program is expected to be a significant element in any future federal action taken to reduce greenhouse gas emissions. ARB's efforts to design a broad cap-and-trade system that works in concert with sector- or source-related measures and meets the requirements of AB 32 can serve as a model for a federal program. An effective, enforceable regional cap-and-trade program can promote the type of federal legislation needed to meet the pressing challenge of climate change. In the event that California businesses, organizations, or individuals hold regional allowances when a federal system is implemented, California will work to ensure that those allowances continue to have value, either in a continuing regional program or within the federal program.

Cap-and-Trade Rulemaking

To implement the cap-and-trade program, ARB will embark on regulatory development that includes extensive and broad-based public participation. Major program design elements will include setting an emissions cap in conjunction with the WCI Partner jurisdictions, determining the method of distributing both allowances and revenues raised through auctions, and establishing the rules for the use of offsets. ARB will continue to work with all affected stakeholders, State and local agencies, and our WCI partners to create a robust regional market system.

After adoption of the Scoping Plan, ARB will establish a formal structure to elicit ongoing participation in the rulemaking process from a wide range of affected stakeholders. While the process will be open to involvement by all interested parties, ARB anticipates creation of a series of focused working groups that include participation by representatives of the regulated community, environmental and community advocates and other public interest groups, prominent academics with expertise in cap-and-trade issues and new technology development, local air pollution control districts, stakeholders in the WCI, and other State agencies with existing authority for regulating capped sectors.

This process will integrate economic and administrative design considerations and include consideration of environmental and public health issues. ARB will convene a series of technical workshops to examine mechanisms to address the concerns related to the cap-and-trade program raised by the Environmental Justice Advisory Committee and other stakeholders. The first workshop will explore cap-and-trade program design options that could provide incentives to maximize additional environmental and economic benefits, and to analyze the proposed program to prevent increases in emissions of toxic air contaminants or criteria pollutants through the design and architecture of the program itself. Similar technical workshops will focus on issues related to offsets and the WCI proposal.

Allowances and Revenues

Emission allowances represent a significant economic value whether they are freely allocated or sold through auction. Section E includes a preliminary discussion of some of the options that have been suggested for use of allowance value or revenues. ARB will evaluate the possible uses of allowances or revenues as part of the rulemaking process. One approach would be to dedicate a portion of the allowances for such purposes as rewarding early actions to reduce emissions, providing incentives for local governments and others to promote energy efficiency, better land use planning, and other reduction strategies, and targeting projects to reduce emissions in low-income or disadvantaged communities. This type of dedicated use of allowances is typically referred to as an allowance 'set-aside.'

The California Public Utilities Commission and the California Energy Commission addressed the question of allocation and auction of allowances in their joint proceeding on implementation of AB 32 for the Electricity and Natural Gas sectors. They have recently released a proposed opinion that recommends to ARB a transition to 100 percent auction for the Electricity sector by 2016.[27] The CPUC and CEC

[27] Op. Cit. The proposed opinion has not yet been voted on by either the CPUC or the CEC. The Commissions are expected to vote on this proposed opinion before the December Board meeting when the Proposed Scoping Plan will be considered for approval.

included in their draft opinion the recommendation that all auction revenues be used for purposes related to AB 32, and all revenue from allowances allocated to the Electricity sector and received by retail providers would be used for the benefit of the Electricity sector to support investments in renewable energy, efficiency, new energy technology, infrastructure, customer bill relief, and other similar programs.

The Market Advisory Committee also recommended the eventual transition to full auction within the cap-and-trade program, noting that a system in which California ultimately auctions all of its emission allowances is consistent with fundamental objectives of cost-effectiveness, fairness and simplicity.[28] ARB agrees that a transition to a 100 percent auction is a worthwhile goal for distributing allowances. However a broad set of factors must be considered in evaluating the potential timing of a transition to a full auction including competiveness, potential for emissions leakage, the effect on regulated vs. unregulated industrial sectors, the overall impact on consumers, and the strategic use of auction revenues.

Allowance allocation and revenue use decisions can greatly affect the equity of a cap-and-trade system. Addressing both these issues will be a major part of the rulemaking process. ARB will seek input from a broad range of experts in an open public process regarding the options for allocation and revenue use under consideration by ARB and the WCI Partner jurisdictions. This process will evaluate various mechanisms ARB is considering for allowance distribution and potential uses of allowance value, including the recommendations offered by CPUC and CEC. Issues to be considered will include the appropriate timing and structure of a transition to full auction of allowances, the potential need to harmonize the allocation process regionally for certain sectors subject to inter-state competition, and equity across the various sectors here in California.

Offsets

Individual projects can be developed to achieve the reduction of emissions from activities not otherwise regulated, covered under an emissions cap, or resulting from government incentives. These projects can generate "offsets," i.e., verifiable reductions of emissions whose ownership can be transferred to others. The cap-and-trade rulemaking will establish appropriate rules for use of offsets. As required by AB 32, any reduction of greenhouse gas emissions used for compliance purposes must be real, permanent, quantifiable, verifiable, enforceable, and additional (HSC §38562(d)(1) and (2)). Offsets used to meet regulatory requirements must be quantified according to Board-adopted methodologies, and ARB must adopt a regulation to verify and enforce the reductions (HSC §38571). The criteria developed will ensure that the reductions are quantified accurately and are not double-counted within the system.

---

[28]Recommendations of the Market Advisory Committee to the California Air Resources Board. *Recommendations for Designing a Greenhouse Gas Cap-and-Trade System for California*. June 30, 2007. p. 55. http://www.climatechange.ca.gov/publications/market_advisory_committee/2007-06-29_MAC_FINAL_REPORT.PDF (accessed October 12, 2008)

Offsets can provide regulated entities a source of low-cost emissions reductions. Reductions from compliance offset projects must be quantified using rigorous measurement and enforcement protocols that provide a basis to determine whether the reductions are also additional, i.e., beyond what would have happened in the absence of the offset project. Establishing that reductions are additional is one of the major challenges in establishing the validity of particular offset projects. Once a project can quantify emissions using an approved methodology, the reductions of emissions must be verified to ensure that reductions actually occurred.

While some offsets provide benefits, allowing unlimited offsets would reduce the amount of reductions of greenhouse gas emissions occurring within the sectors covered by the cap-and-trade program. This could reduce the local economic, environmental and public health co-benefits and delay the transition to low-carbon energy systems within the capped sectors that will be necessary to meet our long term climate goals. The limit on the use of offsets and allowances from other systems within the WCI Partner jurisdiction program design assures that a majority of the emissions reductions required from 2012 to 2020 occur at entities and facilities covered by the cap and trade program. Consequently, the use of offsets and allowances from other systems are limited to no more than 49 percent of the required reduction of emissions. This quantitative limit will help provide balance between the need to achieve meaningful emissions reductions from capped sources with the need to provide sources within capped sectors the opportunity for low-cost reduction opportunities that offsets can provide. The WCI offset program may incorporate flexibility to use offsets and non-WCI allowances across the three compliance periods, which each WCI Partner jurisdiction could use at its discretion. ARB will apply the limit on offsets that is within its jurisdiction, such that the allowable offsets in each compliance period is less than half of the emissions reductions expected from capped sectors in that compliance period. Each WCI Partner jurisdiction may choose to adopt a more stringent limit on the use of offsets and non-WCI allowances.

Offsets can also encourage the spread of clean, low carbon technologies outside California. High quality offset projects located outside the state can help lower the compliance costs for regulated entities in California, while reducing greenhouse gas emissions in areas that would otherwise lack the resources needed to do so. International projects may also have significant environmental, economic and social benefits. Projects in the Mexican border region may be of particular interest, considering the opportunity to realize considerable co-benefits on both sides of the border. The Governor has recently signed a Memorandum of Understanding with the six Mexican border states that calls for cooperation on the development of project protocols for Mexican greenhouse gas emissions reduction projects.[29] Additionally,

[29] Memorandum of Understanding on Environmental Cooperation between the California Environmental Protection Agency, the California Department of Food and Agriculture and the California Resources Agency of the State of California, United States of America and the Ministry of Environment and Natural Resources of the United Mexican States. February 13, 2008. http://gov.ca.gov/pdf/press/021308_MOU_English.pdf (accessed October 12, 2008)

defining project types related to imported commodities (such as cement) would enable California to provide incentives to reduce emissions associated with products that are imported into the state for our consumption.

California is committed to working at the international level to reduce greenhouse gas emissions globally and finding ways to support the adoption of low-carbon technologies and sustainable development in the developing world. ARB will work with WCI Partner jurisdictions and within the rulemaking process to establish an offsets program without geographic restrictions that includes sufficiently stringent criteria for creating offset credits to ensure the overall environmental integrity of the program.

One concept being evaluated for accepting offsets from the developing world is to limit offsets to those jurisdictions that demonstrate performance in reducing emissions and/or achieving greenhouse gas intensity targets in certain carbon intensive sectors (e.g., cement), or in reducing emissions or enhancing sequestration through eligible forest carbon activities in accordance with appropriate national or sub-national accounting frameworks. This could be achieved through an agreement to work jointly to develop minimum performance standards or sectoral benchmarks, backed by appropriate monitoring and accounting frameworks. Such agreements would encourage early action in developing countries toward binding commitments, and could also reduce concerns about competitiveness and risks associated with carbon leakage.

2. California Light-Duty Vehicle Greenhouse Gas Standards

Implement adopted Pavley standards and planned second phase of the program. Align zero-emission vehicle, alternative and renewable fuel and vehicle technology programs with long-term climate change goals.

Passenger vehicles are responsible for almost 30 percent of California's greenhouse gas emissions. To address these emissions, ARB is proposing a comprehensive three-prong strategy – reducing greenhouse gas emissions from vehicles, reducing the carbon content of the fuel these vehicles burn, and reducing the miles these vehicles travel. Transportation fuels and regional transportation-related greenhouse gas targets are discussed later in the recommendations.

There are a number of efforts intended to reduce greenhouse gas emissions from California's passenger vehicles, including the Pavley greenhouse gas vehicle standards to achieve near-term emission reductions, the zero-emission vehicle (ZEV) program to transform the future vehicle fleet, and the Alternative and Renewable Fuel and Vehicle Technology Program created by AB 118 (Núñez, Chapter 750, Statutes of 2007).

Pavley Greenhouse Gas Vehicle Standards

AB 1493 (Pavley, Chapter 200, Statutes of 2002) directed ARB to adopt vehicle standards that lowered greenhouse gas emissions to the maximum extent technologically feasible, beginning with the 2009 model year. ARB adopted regulations in 2004 and applied to the U.S. Environmental Protection Agency (U.S. EPA) for a waiver under the federal Clean Air Act to implement the regulation. The Pavley regulations incorporate both performance standards and market-based compliance mechanisms. To obtain additional reductions from the light duty fleet, ARB plans to adopt a second, more stringent, phase of the Pavley regulations. Table 6 summarizes the estimated reduction of emissions for the Pavley regulations. In addition to delivering greenhouse gas emissions reductions, the standards will save money for Californians who purchase vehicles that comply with the Pavley standards – an estimated average of $30 each month in avoided fuel costs.

To date, 13 other states have adopted California's existing greenhouse gas standards for vehicles. Under federal law, California is the only state allowed to adopt its own vehicle standards (though other states are permitted to adopt California's more rigorous standards), but California cannot implement the regulations until U.S. EPA grants an administrative waiver. In December 2007, U.S. EPA denied California's waiver request to implement the Pavley regulations. California and others are challenging that denial in Federal court. The regulations have also been challenged by the automakers in federal courts, although to date, those challenges have been unsuccessful.

ARB is evaluating the use of feebates as a measure to achieve additional reductions from the mobile source sector, either as a backstop to the Pavley regulation if the regulation cannot be implemented, or as a supplement to Pavley if the waiver is approved and the regulation takes effect. AB 32 specifically states that if the Pavley regulations do not remain in effect, ARB shall implement alternative regulations to control mobile sources to achieve equivalent or greater reductions of greenhouse gas emissions (HSC §38590). ARB is currently evaluating the use of a feebate program as the mechanism to secure these reductions. A feebate regulation would combine a rebate program for low-emitting vehicles with a fee program for high-emitting vehicles. This program would be designed in a way to generate equivalent or greater cumulative reductions of greenhouse gas emissions compared to what would have been achieved under the Pavley regulations. ARB would also evaluate the potential to expand the program to include additional vehicle classes not currently included in the Pavley program for further greenhouse gas benefits.

If the U.S. EPA grants California's request for a waiver to proceed with implementation of the Pavley regulations, we will analyze the potential for pursuing a feebate program that could complement the Pavley regulations and achieve additional reductions of greenhouse gas emissions.

Zero-Emission Vehicle Program

The Zero Emission Vehicle (ZEV) program will play an important role in helping California meet its 2020 and 2050 greenhouse gas emissions reduction requirements. Through 2012, the program requires placement of hundreds of ZEVs (including hydrogen fuel cell and battery electric vehicles) and thousands of near-zero emission vehicles (plug-in hybrids, conventional hybrids, compressed natural gas vehicles). In the mid-term (2012-2015), the program will require placement of increasing numbers of ZEVs and near-zero emission vehicles in California. In 2009, the Board will consider a proposal that is currently being developed to ensure that the ZEV program is optimally designed to help the State meet its 2020 target and put us on the path to meeting our 2050 target of an 80 percent reduction in greenhouse gas emissions.

It is important to note that while the use of both battery-powered electric vehicles and plug-in hybrids (which can be plugged in to recharge batteries) is not expected to increase electricity demand in the near term, over the longer term these technologies could result in meaningful new electricity demand. However, the expected increased electricity demand is likely to be met by off peak vehicle battery charging (i.e., overnight) to provide a means of load leveling and other possible benefits.[30]

Air Quality Improvement Program/Alternative and Renewable Fuel and Vehicle Technology Program

Under AB 118 (Núñez, Chapter 750, Statutes of 2007), ARB is administering the Air Quality Improvement Program, which provides approximately $50 million per year for grants to fund clean vehicle/equipment projects and research on the air quality impacts of alternative fuels and advanced technology vehicles.

AB 118 also created the Alternative and Renewable Fuel and Vehicle Technology Program and authorized CEC to spend up to $120 million per year for over seven years (from 2008-2015) to develop, demonstrate, and deploy innovative technologies to transform California's fuel and vehicle types. This program creates the opportunities for investment in technologies and fuels that will help meet the Low Carbon Fuel Standard, the AB 1007 (Pavley, Chapter 371, Statutes of 2005) goal of increasing alternative fuels, the AB 32 goal of reducing greenhouse gas emissions to 1990 levels by 2020, and the State's overall goal of reducing greenhouse gas emissions 80 percent below 1990 levels by 2050. CEC and ARB are coordinating closely in the implementation of AB 118. In the long-term, programs to reduce greenhouse gas emissions from cars would reduce highway funds because less fuel would be sold, reducing tax revenue. In coordination with other State agencies, ARB will continue to evaluate the potential impacts of these shifts and identify potential solutions.

[30] There is also a potential for battery-electric and hybrid vehicles (both plug-in and traditional hybrid-electric) to be used in the future to provide electricity back into the electricity grid during times of especially high demand (peak periods).

Table 6: California Light-Duty Vehicle Greenhouse Gas Standards Recommendation
($MMTCO_2E$ in 2020)

Measure No.	Measure Description	Reductions
T-1	Pavley I and II – Light-Duty Vehicle Greenhouse Gas Standards	31.7
	Total	**31.7**

3. Energy Efficiency

Maximize energy efficiency building and appliance standards, and pursue additional efficiency efforts including new technologies, and new policy and implementation mechanisms. Pursue comparable investment in energy efficiency from all retail providers of electricity in California (including both investor-owned and publicly-owned utilities).

Energy-efficiency measures for both electricity and natural gas can reduce greenhouse gas emissions significantly. In 2003, the CPUC and CEC adopted an Energy Action Plan that prioritized resources for meeting California's future energy needs, with energy efficiency being first in the "loading order," or highest priority. Since then, this policy goal has been codified into statute through legislation that requires electric utilities to meet their resource needs first with energy efficiency.[31]

This measure would set new targets for statewide annual energy demand reductions of 32,000 gigawatt hours and 800 million therms from business as usual[32] – enough to power more than 5 million homes, or replace the need to build about ten new large power plants (500 megawatts each). These targets represent a higher goal than existing efficiency targets established by CPUC for the investor-owned utilities due to the inclusion of innovative strategies above traditional utility programs. Achieving the State's energy efficiency targets will require coordinated efforts from the State, the federal government, energy companies and customers. ARB will work with CEC and CPUC to facilitate these partnerships. A number of these measures also have the potential to deliver significant economic benefits to California consumers, including low-income households and small businesses. California's energy efficiency programs for buildings and appliances have generated more than $50 billion in savings over the past three decades. Tables 7 and 8 summarize the reduction of greenhouse gas emissions.

[31] SB 1037 (Kehoe, Chapter 366, Statutes of 2005) and AB 2021 (Levine, Chapter 734, Statutes of 2006) directed electricity corporations subject to CPUC's authority and publicly-owned electricity utilities to first meet their unmet resource needs through all available energy efficiency and demand response resources that are cost effective, reliable and feasible.

[32] The savings targeted here are additional to savings currently assumed to be incorporated in CEC's 2007 demand forecasts. However, CEC has initiated a public process to better determine the quantity of energy savings from standards, utility programs, and market effects that are embedded in the baseline demand forecast.

Efficiency

Achieving the energy efficiency target will require redoubled efforts to target industrial, agricultural, commercial, and residential end-use sectors, comprised of both innovative new initiatives that have been embraced by CEC's energy policy reports and CPUC's long-term strategic plan, and improvements to California's traditional approaches of improved building standards and utility programs.

High-efficiency distributed generation applications like fuel cell technologies can also play an important role in helping the State meet its requirements for reduction of greenhouse gas emissions. Key energy efficiency strategies, grouped by type, include:

Cross-cutting Strategy for Buildings
- "Zero Net Energy" buildings[33]

Codes and Standards Strategies
- More stringent building codes and appliance efficiency standards
- Broader standards for new types of appliances and for water efficiency
- Improved compliance and enforcement of existing standards
- Voluntary efficiency and green building targets beyond mandatory codes

Strategies for Existing Buildings
- Voluntary and mandatory whole-building retrofits for existing buildings
- Innovative financing to overcome first-cost and split incentives for energy efficiency, on-site, renewables, and high efficiency distributed generation

Existing and Improved Utility Programs
- More aggressive utility programs to achieve long-term savings

Other Needed Strategies
- Water system and water use efficiency and conservation measures
- Local government programs that lead by example and tap into local authority over planning, development, and code compliance
- Additional industrial and agricultural efficiency initiatives
- Providing real time energy information technologies to help consumers conserve and optimize energy performance

With the support of key State agencies, utilities, local governments and others, the CPUC has recently adopted the *California Long Term Energy Efficiency Strategic Plan*.[34] Released September 2008, this Plan sets forth a set of strategies toward maximizing the achievement of cost-effective energy efficiency in California's Electricity and Natural Gas sectors between 2009 and 2020, and beyond. Its

---

[33] Zero net energy refers to building energy use over the course of a typical year. When the building is producing more electricity than it needs, it exports its surplus to the grid. When the building requires more electricity than is being produced on-site, it draws from the grid. Generally, when constructing a ZNE building, energy efficiency measures can result in up to 70% savings relative to existing building practices, which then allows for renewables to meet the remaining load.

[34] California Public Utilities Commission. *California Long Term Energy Efficiency Strategic Plan.* September 2008. http://www.californiaenergyefficiency.com/docs/EEStrategicPlan.pdf (accessed October 12, 2008).

recommendations are the result of a year-long collaboration by energy experts, utilities, businesses, consumer groups, and governmental organizations in California, throughout the west, nationally and internationally.

For many of the above goals and others, the Strategic Plan discusses practical implementation strategies, detailing necessary partnerships among the state, its utilities, the private sector, and other market players and timelines for near-term, mid-term and long-term success. While the Strategic Plan is the most current and innovative summary of energy efficiency strategies needed to meet State goals, additional planning and new strategies will likely be needed, both to achieve the 2020 emissions reduction goals and to set the State on a trajectory toward 2050.

Other innovative approaches could also be used to motivate private investment in efficiency improvements. One example that will be evaluated during the development of the cap-and-trade program is the creation of a mechanism to make allowances available within the program to provide incentives for local governments, third party providers, or others to pursue projects to reduce greenhouse gas emissions, including the bundling of energy efficiency improvements for small businesses or in targeted communities.

Solar Water Heating

Solar water heating systems offer a potential for natural gas savings in California. A solar water heating system offsets the use of natural gas by using the sun to heat water, typically reducing the need for conventional water heating by about two-thirds. Successful implementation of the zero net energy target for new buildings will require significant growth in California's solar water heating system manufacturing and installation industry. The State has initiated a program to move toward a self sustaining solar water heater industry. The Solar Hot Water and Efficiency Act of 2007 (SHWEA) authorized a ten year, $250-million incentive program for solar water heaters with a goal of promoting the installation of 200,000 systems in California by 2017.[35]

Combined Heat and Power

Combined heat and power (CHP), also referred to as cogeneration, produces electricity and useful thermal energy in an integrated system. The widespread development of efficient CHP systems would help displace the need to develop new, or expand existing, power plants. This measure sets a target of an additional 4,000 MW of installed CHP capacity by 2020, enough to displace approximately 30,000 GWh of demand from other power generation sources.[36]

[35] Established under Assembly Bill 1470 (Huffman, Chapter 536, Statues of 2007).

[36] Accounting for avoided transmission line losses of seven percent, this amount of CHP would actually displace 32,000 GWh from the grid.

California has supported CHP for many years, but market and other barriers continue to keep CHP from reaching its full market potential. Increasing the deployment of efficient CHP will require a multi-pronged approach that includes addressing significant barriers and instituting incentives or mandates where appropriate. These approaches could include such options as utility-provided incentive payments, the creation of a CHP portfolio standard, transmission and distribution support payments, or the use of feed-in tariffs.

Table 7: Energy Efficiency Recommendation - Electricity
($MMTCO_2E$ in 2020)

Measure No.	Measure Description	Reductions
E-1	Energy Efficiency (32,000 GWh of Reduced Demand) • Increased Utility Energy Efficiency Programs • More Stringent Building & Appliance Standards • Additional Efficiency and Conservation Programs	15.2
E-2	Increase Combined Heat and Power Use by 30,000 GWh	6.7
	Total	**21.9**

Table 8: Energy Efficiency Recommendation - Commercial and Residential
($MMTCO_2E$ in 2020)

Measure No.	Measure Description	Reductions
CR-1	Energy Efficiency (800 Million Therms Reduced Consumption) • Utility Energy Efficiency Programs • Building and Appliance Standards • Additional Efficiency and Conservation Programs	4.3
CR-2	Solar Water Heating (AB 1470 goal)	0.1
	Total	**4.4**

4. Renewables Portfolio Standard

Achieve 33 percent renewable energy mix statewide.

CEC estimates that about 12 percent of California's retail electric load is currently met with renewable resources. Renewable energy includes (but is not limited to) wind, solar, geothermal, small hydroelectric, biomass, anaerobic digestion, and landfill gas. California's current Renewables Portfolio Standard (RPS) is intended to increase that share to 20 percent by 2010. Increased use of renewables will decrease California's reliance on fossil fuels, thus reducing emissions of greenhouse gases from the Electricity sector. Based on Governor Schwarzenegger's call for a statewide 33 percent RPS, the Plan anticipates that California will have 33 percent of its electricity provided by renewable resources by 2020, and includes the reduction of greenhouse gas emissions based on this level.

Senate Bill 107 (Simitian, Chapter 464, Statutes of 2006) obligates the investor-owned utilities (IOUs) to increase the share of renewables in their electricity portfolios to 20 percent by 2010. Meanwhile, the publicly-owned utilities (POUs) are encouraged but not required to meet the same RPS. The governing boards of the state's three largest POUs, the Los Angeles Department of Water and Power (LADWP), the Sacramento Municipal Utility District (SMUD), and the Imperial Irrigation District (IID), have adopted policies to achieve 20 percent renewables by 2010 or 2011. LADWP and IID have established targets of 35 and 30 percent, respectively, by 2020.

In 2005, CEC and CPUC committed in the Energy Action Plan II to "evaluate and develop implementation paths for achieving renewable resource goals beyond 2010, including 33 percent renewables by 2020, in light of cost-benefit and risk analysis, for all load serving entities." The proposed opinion in the CPUC/CEC joint proceeding lends strong support for obtaining 33 percent of California's electricity from renewables, and states the two Commissions' belief that this target is achievable if the State commits to significant investments in transmission infrastructure and key program augmentation. As with the energy efficiency target, achieving the 33 percent goal will require broad-based participation from many parties and the removal of barriers. CEC, CPUC, California Independent System Operator (CAISO), and ARB are working with California utilities and other stakeholders to formally establish and meet this goal.

A key prerequisite to reaching a target of 33 percent renewables will be to provide sufficient electric transmission lines to renewable resource zones and system changes to allow integration of large quantities of intermittent wind and solar generation. The Renewable Energy Transmission Initiative (RETI) is a broad collaborative of State agencies, utilities, the environmental community, and renewable generation developers that are working cooperatively to identify and prioritize renewable generation zones and associated transmission projects. Although biomass, geothermal, and small-scale hydroelectric generation can provide steady baseload power, other renewable generation is intermittent (wind) or varies over time (solar). Therefore, integration of intermittent generation into the electricity system will require grid improvements so that fluctuations in power availability can be accommodated. Improved communications technology, automated demand response, electric sub-station improvements and other modern technologies must be implemented both to facilitate intermittent renewables, and to improve grid reliability.

Another key action that may help to achieve the renewable energy goals is to reduce the complexity and cost faced by small renewable developers in contracting with utilities to supply renewable generation. This is particularly important for projects offering below 20 megawatts of generation capacity. One such option may be a feed-in tariff for all RPS-eligible renewable energy facilities up to 20 megawatts in size. This mechanism was recommended in CEC's 2007 Integrated Energy Policy Report. Such a tariff, set at an appropriate level, could benefit small-scale facilities by allowing them to be brought into the electricity grid more rapidly.

For the purposes of calculating the reduction of greenhouse gas emissions in this Proposed Scoping Plan, ARB is counting emissions avoided by increasing the percentage of renewables in California's electricity mix from the current level of 12 percent to the 33 percent goal, as shown in Table 9.

Table 9: Renewables Portfolio Standard Recommendation
($MMTCO_2E$ in 2020)

Measure No.	Measure Description	Reductions
E-3	Achieve a 33% renewables mix by 2020	21.3
	Total	**21.3**

5. Low Carbon Fuel Standard

Develop and adopt the Low Carbon Fuel Standard.

Because transportation is the largest single source of greenhouse gas emissions in California, the State is taking an integrated approach to reducing emissions from this sector. Beyond including vehicle efficiency improvements and lowering vehicle miles traveled, the State is proposing to reduce the carbon intensity of transportation fuels consumed in California.

To reduce the carbon intensity of transportation fuels, ARB is developing a Low Carbon Fuel Standard (LCFS), which would reduce the carbon intensity of California's transportation fuels by at least ten percent by 2020 as called for by Governor Schwarzenegger in Executive Order S-01-07.

LCFS will incorporate compliance mechanisms that provide flexibility to fuel providers in how they meet the requirements to reduce greenhouse gas emissions. The LCFS will examine the full fuel cycle impacts of transportation fuels and ARB will work to design the regulation in a way that most effectively addresses the issues raised by the Environmental Justice Advisory Committee and other stakeholders. ARB identified the LCFS as a Discrete Early Action item, and is developing a regulation for Board consideration in March 2009. A 10 percent reduction in the intensity of transportation fuels is expected to equate to a reduction of 16.5 $MMTCO_2E$ in 2020. However, in order to account for possible overlap of benefits between LCFS and the Pavley greenhouse gas standards, ARB has discounted the contribution of LCFS to 15 $MMTCO_2E$.

Table 10: Low Carbon Fuel Standard Recommendation
(MMTCO_2E in 2020)

Measure No.	Measure Description	Reductions
T-2	Low Carbon Fuel Standard (Discrete Early Action)	15
	Total	**15**

6. Regional Transportation-Related Greenhouse Gas Targets

Develop regional greenhouse gas emissions reduction targets for passenger vehicles.

Establishment of Regional Targets

On September 30, 2008, Governor Arnold Schwarzenegger signed Senate Bill 375 (Steinberg) which establishes mechanisms for the development of regional targets for reducing passenger vehicle greenhouse gas emissions. Through the SB 375 process, regions will work to integrate development patterns and the transportation network in a way that achieves the reduction of greenhouse gas emissions while meeting housing needs and other regional planning objectives. This new law reflects the importance of achieving significant additional reductions of greenhouse gas emissions from changed land use patterns and improved transportation to help achieve the goals of AB 32.

SB 375 requires ARB to develop, in consultation with metropolitan planning organizations (MPOs), passenger vehicle greenhouse gas emissions reduction targets for 2020 and 2035 by September 30, 2010. It sets forth a collaborative process to establish these targets, including the appointment by ARB of a Regional Targets Advisory Committee to recommend factors to be considered and methodologies for setting greenhouse gas emissions reduction targets. SB 375 also provides incentives – relief from certain California Environmental Quality Act (CEQA) requirements for development projects that are consistent with regional plans that achieve the targets.

Reaching the Targets

Transportation planning is done on a regional level in major urban areas, through the Metropolitan Planning Organizations. These MPOs are required by the federal government to prepare regional transportation plans (RTPs) in order to receive federal transportation dollars. These plans must reflect the land uses called out in city and county general plans. Regional planning efforts provide an opportunity for community residents to help select future growth scenarios that lead to more sustainable and energy efficient communities. Such plans should be developed through an extensive public process to provide for local accountability.

SB 375 requires MPOs to prepare a sustainable communities strategy to reach the regional target provided by ARB. MPOs would use the sustainable communities strategy for the land use pattern underlying the region's transportation plan. If the strategy does not meet the target, the MPO must document the impediments and show how the target could be met with an alternative planning strategy. The CEQA relief would be provided to those projects that are consistent with either the sustainable communities strategy or alternative planning strategy, whichever meets the target.

Many regions in California have conducted comprehensive scenario planning, called Blueprint planning, that engages a broad set of stakeholders at the local level on the impacts of land use and transportation choices. The State has allocated resources to initiate or augment existing Blueprint efforts of MPOs. These efforts focus on fostering efficient land use patterns that not only reduce vehicle travel but also accommodate an adequate supply of housing, reduce impacts on valuable habitat and productive farmland, increase resource use efficiency, and promote a prosperous regional economy. Blueprint planning can play an important role in the SB 375 process by helping inform target-setting efforts and building strong sustainable communities strategies.

Local governments will play a significant role in the regional planning process to reach passenger vehicle greenhouse gas emissions reduction targets. Local governments have the ability to directly influence both the siting and design of new residential and commercial developments in a way that reduces greenhouse gases associated with vehicle travel, as well as energy, water, and waste. A partnership of local and regional agencies is needed to create a sustainable vision for the future that accommodates population growth in a carbon efficient way while meeting housing needs and other planning goals. Integration of the sustainable communities strategies or alternative planning strategies with local general plans will be key to the achievement of these goals. State, regional, and local agencies must work together to prioritize and create the supporting policies, programs, incentives, guidance, and funding to assist local actions to help ensure regional targets are met.

Enhanced public transit service combined with incentives for land use development that provides a better market for public transit will play an important role in helping to reach regional targets.

SB 375 maintains regions' flexibility in the development of sustainable communities strategies. There are many different ways regions can plan and work toward reducing the growth in vehicle travel. Increasing low-carbon travel choices (public transit, carpooling, walking and biking) combined with land use patterns and infrastructure that support these low-carbon modes of travel, can decrease average vehicle trip lengths by bringing more people closer to more destinations. The need for integrated strategies is supported by the current transportation and land use modeling literature.

Supporting measures that should be considered in both the regional target-setting and sustainable communities strategy processes include the following:

- Congestion pricing strategies can provide a method of efficiently managing traffic demand while raising funds for needed transit, biking and pedestrian infrastructure investment. Regional and local agencies, however, do not have the authority to pursue these strategies on their own, as federal approval and State authorization must be provided for regional implementation of most pricing measures.

- Indirect source rules for new development have already been implemented by some local air districts and proposed by others for purposes of criteria pollution reduction. Regions should evaluate the need for measures that would ensure the mitigation of high carbon footprint development outside of the sustainable communities strategies or alternative planning strategies that meet the targets established under SB 375.

- Programs to reduce vehicle trips while preserving personal mobility, such as employee transit incentives, telework programs, car sharing, parking policies, public education programs and other strategies that enhance and complement land use and transit strategies can be implemented and coordinated by regional and local agencies and stakeholder groups.

Another way to encourage greenhouse gas reductions from vehicle travel is through pay as you drive insurance (PAYD), a structure in which drivers realize a direct financial benefit from driving less. The California Insurance Commissioner recently announced support for PAYD and has proposed regulations to permit PAYD on a voluntary basis.

Separate emissions reduction estimates for these strategies are not quantified here. As regional targets are developed in the SB 375 process, ARB will work with regions to quantify the benefits in the context of the targets.

Estimating the Benefits of Regional Targets

The ARB estimate of the statewide benefit of regional transportation-related greenhouse gas emissions reduction targets is based on analysis of research results quantifying the effects of land use and transportation strategies. The emissions reduction number in Table 11 is not the statewide metric for regional targets that must be developed as SB 375 is implemented. The emissions target will ultimately be determined during the SB 375 process.

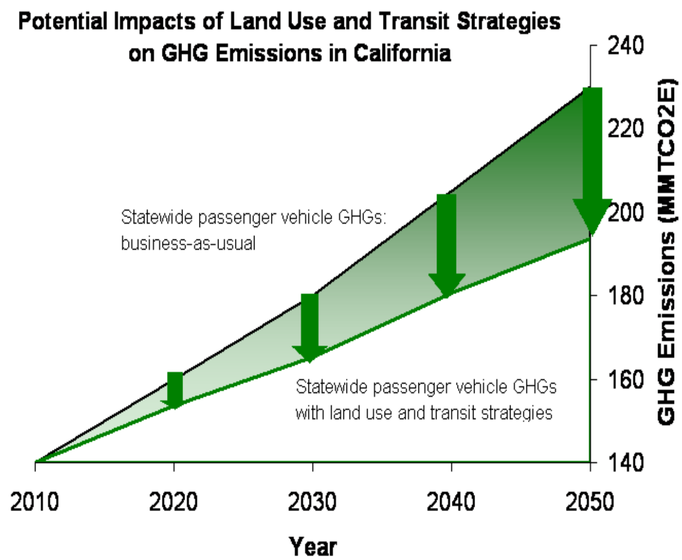
The possible impacts of land use and transportation policies have been well documented. Most recently, a 2008 U.C. Berkeley study[37] reviewed over 20 modeling studies from California (including the State's four largest MPOs), other states and Europe. The study found a range of 0.4 to 7.7 percent reduction in vehicle miles traveled (VMT) resulting from a combination of land use and enhanced transit policies compared to a business-as-usual case over a 10-year horizon, with benefits doubling by 2030, as shown in Figure 4. With the inclusion of additional measures

---

[37] Rodier, Caroline. U.C. Berkeley, Transportation Sustainability Research Center, "A Review of the International Modeling Literature: Transit, Land Use, and Auto Pricing Strategies to Reduce Vehicle Miles Traveled and Greenhouse Gas Emissions," August 2008. http://www.arb.ca.gov/planning/tsaq/docs/rodier_8-1-08_trb_paper.pdf (accessed October 12, 2008)

such as pricing policies, the reduction of greenhouse gas emissions can be greater. These strategies will be considered during the target-setting process. Sophisticated land use and transportation models can best assess these effects. As part of the development of regional targets, technical tools will need to be refined to ensure sound quantification techniques are available.

Figure 4



The potential benefits of this measure that can be realized by 2020 (as shown in Table 11) were estimated after first accounting for the benefits of the vehicle technology and efficiency measures in the plan. It was calculated based on the U.C. Berkeley study's median value of 4 percent per capita VMT reduction over a 10-year time horizon. This value should not be interpreted as the final estimate of the benefits of this measure. The current academic literature supports this realistic statewide estimate of potential benefits, but the ultimate benefit will be determined as an outcome of SB 375 implementation on a regional level. The incentives for sustainable planning in SB 375 can set California on a new path. ARB's establishment of regional targets in 2010, combined with the Regional Targets Advisory Committee process, required by the legislation, provides a clear mechanism for maximizing the benefits of this measure.

Additional Benefits of Regional Targets and Land Use Strategies

Land use and transportation measures that help reduce vehicle travel will also provide multiple benefits beyond greenhouse gas reductions. Quality of life will be improved by increasing access to a variety of mobility options such as transit, biking, and walking, and will provide a diversity of housing options focused on proximity to jobs, recreation, and services. Other important state and community goals that could be met through better integrated land use and transportation planning include agricultural, open space and habitat preservation, improved water quality, positive health effects, and the reduction of smog forming pollutants.

Growing more sustainably has the potential to provide additional greenhouse gas and energy savings by encouraging more compact, mixed-use developments resulting in reduced demand for electricity and heating and cooling energy. These land use-related energy savings will contribute toward the Plan's energy efficiency measures to achieve the goal of reducing electricity and natural gas usage. ARB is continuing to evaluate the greenhouse gas emissions reductions that may be additional to the proposed measures in this plan.

Table 11: Regional Transportation-Related Greenhouse Gas Targets Recommendation
($MMTCO_2E$ in 2020)

Measure No.	Measure Description	Reductions
T-3	Regional Transportation-Related Greenhouse Gas Targets[38]	5
	Total	**5**

7. Vehicle Efficiency Measures

Implement light-duty vehicle efficiency measures.

Several additional measures could reduce light-duty vehicle greenhouse gas emissions. The California Integrated Waste Management Board (CIWMB) with various partners continues to conduct a public awareness campaign to promote sustainable tire practices. ARB is pursuing a regulation to ensure that tires are properly inflated when vehicles are serviced. In addition, CEC in consultation with CIWMB is developing an efficient tire program focusing first on data gathering and outreach, then on potential adoption of minimum fuel-efficient tire standards, and lastly on the development of consumer information requirements for replacing tires. ARB is also pursuing ways to reduce engine load via lower friction oil and reducing the need for air conditioner use. ARB is actively engaged in the regulatory development process for the tire inflation component of this measure. Current information indicates the reduction of greenhouse gas emissions is likely to be less than estimated in the Draft Scoping Plan. ARB has adjusted the estimated reductions shown in Table 12 to reflect this.

[38] This number represents an estimate of what may be achieved from local land use changes. It is not the SB 375 regional target. ARB will establish regional targets for each MPO region following the input of the Regional Targets Advisory Committee and a public consultation process with MPOs and other stakeholders per SB 375.

Table 12: Vehicle Efficiency Recommendation
($MMTCO_2E$ in 2020)

Measure No.	Measure Description	Reductions
T-4	Vehicle Efficiency Measures	4.5
	Total	**4.5**

8. Goods Movement

Implement adopted regulations for the use of shore power for ships at berth. Improve efficiency in goods movement activities.

A significant portion of greenhouse gas emissions from transportation activities comes from the movement of freight or goods throughout the state. Activity at California ports is forecast to increase by 250 percent between now and 2020. Both the Goods Movement Emission Reduction Plan (GMERP) and the 2007 State Implementation Plan (SIP) contain numerous measures designed to reduce the public health impact of goods movement activities in California. ARB has already adopted a regulation to require ship electrification at ports. Proposition 1B funds, as well as clean air plans being implemented by California's ports, will also help reduce greenhouse gas emissions while cutting criteria pollutant and toxic diesel emissions. ARB is proposing to develop and implement additional measures to reduce greenhouse gas emissions due to goods movement from trucks, ports and other related facilities. The anticipated reductions would be above and beyond what is already expected in the GMERP and the SIP. This effort should provide accompanying reductions in air toxics and smog forming emissions. The estimated reduction of greenhouse gas emissions is shown in Table 13.

After further evaluation, ARB incorporated the Draft Scoping Plan's Heavy-Duty Vehicle-Efficiency measure into the Goods Movement measure. A Heavy-Duty Engine Efficiency measure could reduce emissions associated with goods movement through improvements which could involve advanced combustion strategies, friction reduction, waste heat recovery, and electrification of accessories. ARB will consider setting requirements and standards for heavy-duty engine efficiency in the future if higher levels of efficiency are not being produced either in response to market forces (fuel costs) or federal standards.

T-5	Ship Electrification at Ports (Discrete Early Action)	0.2
T-6	Goods Movement Efficiency Measures • System-Wide Efficiency Improvements	3.5
	Total	**3.7**

9. Million Solar Roofs Program

Install 3,000 MW of solar-electric capacity under California's existing solar programs.

As part of Governor Schwarzenegger's Million Solar Roofs Program, California has set a goal to install 3,000 megawatts (MW) of new solar capacity by 2017 – moving the state toward a cleaner energy future and helping lower the cost of solar systems for consumers. The Million Solar Roofs Initiative is a ratepayer-financed incentive program aimed at transforming the market for rooftop solar systems by driving down costs over time. Created under Senate Bill 1 (Murray, Chapter 132, Statutes of 2006), the Million Solar Roofs Program includes CPUC's California Solar Initiative and CEC's New Solar Homes Partnership, and requires publicly-owned utilities (POUs) to adopt, implement and finance a solar incentive program. This measure would offset electricity from the grid, thereby reducing greenhouse gas emissions. The estimated emissions reductions are shown in Table 14.

Obtaining the incentives requires the building owners or developers to meet certain efficiency requirements: specifically, that new construction projects meet energy efficiency levels that exceed the State's Title 24 Building Energy Efficiency Standards, and that existing commercial buildings undergo an energy audit. Thus, the program is also a mechanism for achieving the efficiency targets for the Energy sector. By requiring greater energy efficiency for projects that seek solar incentives, the State would be able to reduce both electricity and natural gas needs and their associated greenhouse gas emissions.

Table 14: Million Solar Roofs Recommendation
($MMTCO_2E$ in 2020)

Measure No.	Measure Description	Reductions
E-4	Million Solar Roofs (including California Solar Initiative, New Solar Homes Partnership and solar programs of publicly owned utilities) • Target of 3000 MW Total Installation by 2020	2.1
	Total	**2.1**

10. Medium/Heavy-Duty Vehicles

Adopt medium and heavy-duty vehicle efficiency measures.

Medium- and heavy-duty vehicles account for approximately 20 percent of the transportation greenhouse gas inventory. Requiring retrofits to improve the fuel efficiency of heavy-duty trucks could include a requirement for devices that reduce aerodynamic drag and rolling resistance. In addition, hybridization of medium- and heavy-duty vehicles would also reduce greenhouse gas emissions through increased fuel efficiency. Hybrid trucks would likely achieve the greatest benefits in urban, stop-and-go applications, such as parcel delivery, utility services, transit, and other vocational work trucks. The recommendation for this sector is summarized in Table 15.

Table 15: Medium/Heavy-Duty Vehicle Recommendation
(MMTCO_2E in 2020)

Measure No.	Measure Description	Reductions
T-7	Heavy-Duty Vehicle Greenhouse Gas Emissions Reduction Measure - Aerodynamic Efficiency (Discrete Early Action)	0.9
T-8	Medium/Heavy-Duty Vehicle Hybridization	0.5
	Total	**1.4**

11. Industrial Emissions

Require assessment of large industrial sources to determine whether individual sources within a facility can cost-effectively reduce greenhouse gas emissions and provide other pollution reduction co-benefits. Reduce greenhouse gas emissions from fugitive emissions from oil and gas extraction and gas transmission. Adopt and implement regulations to control fugitive methane emissions and reduce flaring at refineries.

Energy Efficiency and Co-Benefits Audits for Large Industrial Sources

This measure would apply to the direct greenhouse gas emissions at major industrial facilities emitting more than 0.5 MMTCO_2E per year. In general, these facilities also have significant emissions of criteria air pollutants, toxic air pollutants, or both. Major industrial facilities include power plants, refineries, cement plants, and miscellaneous other sources. ARB would implement this measure through a regulation, requiring each facility to conduct an energy efficiency audit of individual combustion and other direct sources of greenhouse gases within the facility to determine the potential reduction opportunities, including criteria air pollutants and toxic air contaminants. The audit would include an assessment of the impacts of replacing or upgrading older, less efficient units such as boilers and heaters, or replacing the units with combined heat and power (CHP) units. The measure is summarized in Table 16.

The audit would help ARB to identify potential reductions of greenhouse gas emissions reductions, the associated costs and cost-effectiveness, their technical feasibility, and the potential to reduce air pollution impacts at the local or regional level. ARB will use the results to determine if certain emissions sources within a facility can make cost-effective reductions of greenhouse gas emissions that also provide reductions in other criteria or toxic pollutants. Where this is the case, rule provisions or permit conditions would be considered to ensure the best combination of pollution reductions. Nothing in this measure would delay known cost-effective strategies that otherwise would be required.

The California Long Term Energy Efficiency Strategic Plan (CPUC) discusses a number of strategies associated with improving industrial sector efficiency and greenhouse gas emissions reductions, including the development of certification protocols for industrial efficiency improvements to develop market recognition for efficiency gains.

Oil and Gas Recovery Operations and Transmission/Refineries

California is a major oil and gas producer. Crude oil, both from in-state and imported sources, is processed at 21 oil refineries in the state. In addition to conforming to the requirements of the cap-and-trade program and the audit measure, ARB has identified four specific measures for development and implementation, two for oil and gas recovery operations and gas transmission, and two for refineries. Other industrial measures that were under consideration affect greenhouse gas emissions sources that are fully regulated under cap and trade, which ARB concluded would provide cost-effective reductions of greenhouse gas emissions. All measures would be designed to secure a combination of cost-effective reductions in greenhouse gas emissions, criteria air pollutants and air toxics. Two measures would be developed to reduce methane emissions in the oil and gas production and gas transmission processes from leaks and incomplete combustion of methane (used as fuel). These measures would include improved leak detection, process modifications, equipment retrofits, installation of new equipment, and best management practices. The first measure would affect oil and gas producers. The second would impact operators of natural gas pipeline systems. These fugitive emissions are not proposed to be covered by a cap and trade program, although combustion-related emissions from these operations are proposed to be covered. The WCI partner jurisdictions are currently evaluating the inclusion of fugitive methane emissions to the extent that adequate quantification methods exist. During implementation of this measure, ARB will determine whether these emissions will also be covered in California's cap-and-trade program. If the emissions are covered under the cap, ARB will evaluate the need for the measures described here.

Two measures would be developed for oil refineries. The first would limit the greenhouse gas emissions from refinery flares while preserving flaring as needed for safety reasons. The second would remove the current fugitive methane exemption in most refinery Volatile Organic Compounds (VOC) regulations. This exemption was established because methane does not appreciably contribute to urban smog, but is inappropriate given the role that methane plays in global warming. ARB believes these measures would provide cost-effective greenhouse gas, criteria pollutants and air toxics emissions reductions. Most combustion and other process emissions at refineries would be governed by the cap-and-trade program. As with the oil and gas production measures above, the need for these measures would be evaluated if fugitive methane is included in the WCI cap-and-trade program.

I-5	Removal of Methane Exemption from Existing Refinery Regulations	0.01
	Total	**1.4**

12. High Speed Rail

Support implementation of a high speed rail system.

A high speed rail (HSR) system is part of the statewide strategy to provide more mobility choice and reduce greenhouse gas emissions. This measure supports implementation of plans to construct and operate a HSR system between northern and southern California. As planned, the HSR is a 700-mile-long rail system capable of speeds in excess of 200 miles per hour on dedicated, fully-grade separated tracks with state-of-the-art safety, signaling and automated rail control systems. The system would serve the major metropolitan centers of California in 2030 and is projected to displace between 86 and 117 million riders from other travel modes in 2030.

For Phase 1 of the HSR, between San Francisco and Anaheim, 2020 is projected to be the first year of service, with 26 percent of the projected 2030 full system ridership levels. The anticipated reduction of greenhouse gas emissions are shown in Table 17. HSR system ridership and the benefits associated with it are anticipated to increase over time as additional portions of the planned system are completed. Over the long term, the system also has the potential to support the reduction of greenhouse gas emissions in the transportation sector from land use strategies, by providing opportunities for and encouraging low-impact transit-oriented development.

HSR implementation is dependent on voter approval, and the “Safe, Reliable High-Speed Passenger Train Bond Act for the 21st Century” will appear on the November 2008 ballot as Proposition 1A. If Proposition 1A is approved, construction of HSR is anticipated to begin in 2010, with full implementation anticipated in 2030.

	Total	**1.0**

13. Green Building Strategy

Expand the use of green building practices to reduce the carbon footprint of California's new and existing inventory of buildings.

Collectively, energy use and related activities by buildings are the second largest contributor to California's greenhouse gas emissions. Almost one-quarter of California's greenhouse gas emissions can be attributed to buildings.[39] As the Governor recognized in his Green Building Initiative (Executive Order S-20-04), significant reductions in greenhouse gas emissions can be achieved through the design and construction of new green buildings as well as the sustainable operation, retrofitting, and renovation of existing buildings.

A Green Building strategy offers a comprehensive approach to reducing direct and upstream greenhouse gas emissions that cross-cuts multiple sectors including Electricity/Natural Gas, Water, Recycling/Waste, and Transportation. Green buildings are designed, constructed, renovated, operated, and maintained using an integrated approach that reduces greenhouse gas emissions by maximizing energy and resource efficiency. Employing a whole-building design approach can create tremendous synergies that result in multiple benefits at little or no net cost, allowing for efficiencies that would never be possible on an incremental basis.

A Green Building strategy will produce greenhouse gas saving through buildings that exceed minimum energy efficiency standards, decrease consumption of potable water, reduce solid waste during construction and operation, and incorporate sustainable materials. Combined these measures can also contribute to healthy indoor air quality, protect human health and minimize impacts to the environment. A Green Building strategy also includes siting considerations. Buildings that are sited close to public transportation or near mixed-use areas can work in tandem with transportation-related strategies to decrease greenhouse gas emissions that result from that sector.

In July 2008, the California Building Standards Commission (CBSC) adopted the Green Building Standards Code (GBSC) for all new construction in the state. While the current version of the commercial green building code is voluntary, CBSC anticipates adopting a mandatory code in 2011 which will institute minimum environmental performance standards for all occupancies. The Green Building Strategy includes Zero Net Energy (ZNE) goals for new and existing homes and commercial buildings consistent with the recently-adopted California Long Term Energy Efficiency Strategic Plan. ARB encourages local governments to raise the bar by adopting "beyond-code" green building requirements. To assist this effort, State government would develop and regularly tighten voluntary standards, written in GBSC language for easy adoption by local jurisdictions.

[39] Greenhouse gas emission estimates from electricity, natural gas, and water use in homes and commercial buildings.

As we approach the 2020 and 2030 targets for zero energy buildings, these "percent above code" targets must shift to "percent of ZNE" targets. Zero energy new and existing buildings can be an overarching and unifying concept for energy efficiency in buildings, as discussed above (building energy efficiency measures E-1 and CR-1). In order to achieve statewide GHG emission reductions, these targets should be expanded to address other aspects of environmental performance. For example, these targets could be re-framed as a carbon footprint reduction goal for a 35 percent reduction in both energy and water consumption. For commercial buildings, a 2011 target should be established such that a quarter of all new buildings reduce energy and water consumption by at least 25 percent beyond code.

Furthermore, retrofitting existing residential and commercial buildings would achieve substantial greenhouse gas emissions reduction benefits. This Proposed Scoping Plan recommends the establishment of an environmental performance rating system for homes and commercial buildings and further recommends that California adopt mechanisms to encourage and require retrofits for buildings that do not meet minimum standards of performance.

An effective green building framework can operate to deliver reductions of greenhouse gas emissions in multiple sectors. The green building strategies provide a vehicle to achieve the statewide electricity and natural gas efficiency targets and lower greenhouse gas emissions from the waste and water transport sectors. Achieving these green building emissions reductions will require coordinated efforts from a broad range of stakeholders, and new financing mechanisms to motivate investment in green building strategies.

Achieving significant greenhouse gas emissions reductions from new and existing buildings will require a combination of green building measures for new construction and retrofits to existing buildings. The State of California will set an example by requiring all new State buildings to exceed existing Green Building Initiative energy goals and achieve nationally-recognized building sustainability standards such as Leadership in Energy and Environmental Design - New Construction (LEED-NC) "Gold" certification. Existing State buildings would also be retrofitted to achieve higher standards equivalent to LEED-EB for existing buildings (EB) "Silver." All new schools should be required to meet the Collaborative for High Performance Schools (CHPS) 2009 criteria. Existing schools applying for modernization funds should also be required to meet CHPS 2009 criteria.

ARB estimates that the greenhouse gas savings from green building measures as approximately 26 $MMTCO_2E$, as shown in Table 18 below. Most of these reductions are accounted for in the Electricity, Waste, Water, and Transportation sectors. Because of this, ARB has assigned all emissions reductions that occur as a result of green building strategies to other sectors for purposes of meeting AB 32 requirements, but will continue to evaluate and refine the emissions from this sector. As such, this strategy will require implementation from various entities within

California, including CEC, PUC, State Architect, and others, each taking the lead in their area of authority and expertise.

Table 18: Green Buildings Recommendation
(MMTCO_2E in 2020)

Measure No.	Measure Description	Reductions
GB-1	Green Buildings[40]	26
	Total	**26**

14. High Global Warming Potential Gases

Adopt measures to reduce high global warming potential gases.

High global warming potential (GWP) gases pose a unique challenge. Just a few pounds of high GWP materials can have the equivalent effect on global warming as several *tons* of carbon dioxide. For example, the average refrigerator has about a half-pound of refrigerant and about one pound of “blowing agents” used to make the insulating foam. If these gases were released into the atmosphere, they would have a global warming impact equivalent to five metric tons of CO_2.

High GWP chemicals are very common and are used in many different applications such as refrigeration, air conditioning systems, fire suppression systems, and the production of insulating foam. Because these gases have been in use for years, old refrigerators, air conditioners and foam insulation represent a significant “bank” of these materials yet to be released. High GWP gases are released primarily in two ways. The first is through leaking systems, and the second is during the disposal process. Once high GWP materials are released, they persist in the atmosphere for tens or even hundreds of years. Recommended measures to address this growing problem take the form of direct regulations and use of mitigation fees.

ARB identified four Discrete Early Action measures to reduce greenhouse gas emissions from the refrigerants used in car air conditioners, semiconductor manufacturing, air quality tracer studies, and consumer products. ARB has identified additional potential reduction opportunities based on specifications for future commercial and industrial refrigeration, changing the refrigerants used in auto air conditioning systems, and ensuring that existing car air conditioning systems as well as stationary refrigeration equipment do not leak. Recovery and destruction of high GWP materials in the banks described above could also provide significant reductions.

[40] Although some of these emissions reductions may be additional, most of them are accounted for in the Energy, Waste, Water, and Transportation sectors. In addition, some of these reductions may occur out of state, making quantification more difficult. Because of this, these emissions reductions are not currently counted toward the AB 32 2020 goal.

ARB is also proposing to establish an upstream mitigation fee on the use of high GWP gases. Even with the reductions from the specific high GWP measures described above, this sector's emissions are still projected to more than double from current levels by 2020. This is because of the high growth in the sector due, in part, to the replacement of ozone-depleting substances being phased out of production. These emissions would be difficult to address via traditional approaches since the gases are used in small quantities in very diverse applications. Additionally, there are no proven substitutes or alternatives for some uses, and the relative low price of most high GWP compounds provides little incentive to develop alternatives, reduce leakage, or recover the gases at end-of-life.

An upstream fee would ensure that the climate impact of these substances is reflected in the total cost of the product, encouraging reduced use and end-of-life losses, as well as the development of alternatives. The fee would be variable and associated with the impact the product makes on public health and the environment. This could encourage product innovation because fees would correspondingly decrease as the manufacturer or producer redesigned their product or found lower-cost alternatives. This mitigation fee would complement many of the downstream high GWP regulations currently being developed.[41] Fees on high GWP gases would be set to be consistent with the cost of reducing greenhouse gas emissions and could be set to reduce multiple environmental impacts. Revenues could be used to mitigate greenhouse gas emissions either from other high GWP compounds or other greenhouse gases.

Table 19 summarizes the recommendations for measures in the High GWP sector. These measures address both high GWP gases identified in AB 32 and also other high GWP gases, such as ozone-depleting substances that are only partially covered by the Montreal Protocol. The emissions reductions shown are only for the six greenhouse gases explicitly identified in AB 32.

[41] Industrial process emissions of high GWP gases are also expected to be part of the cap-and-trade program. As ARB moves through the rulemaking for both the high GWP fee and the cap-and-trade program, staff will evaluate whether these are complementary approaches or if one or the other needs to be adjusted to prevent duplicative regulation of the industrial process emissions of these gases.

Table 19: High GWP Gases Sector Recommendation
($MMTCO_2E$ in 2020)

Measure No.	Measure Description	Reductions
H-1	Motor Vehicle Air Conditioning Systems: Reduction of Refrigerant Emissions from Non-Professional Servicing (Discrete Early Action)	0.26
H-2	SF_6 Limits in Non-Utility and Non-Semiconductor Applications (Discrete Early Action)	0.3
H-3	Reduction of Perfluorocarbons in Semiconductor Manufacturing (Discrete Early Action)	0.15
H-4	Limit High GWP Use in Consumer Products (Discrete Early Action) (Adopted June 2008)	0.25
H-5	High GWP Reductions from Mobile Sources • Low GWP Refrigerants for New Motor Vehicle Air Conditioning Systems • Air Conditioner Refrigerant Leak Test During Vehicle Smog Check • Refrigerant Recovery from Decommissioned Refrigerated Shipping Containers • Enforcement of Federal Ban on Refrigerant Release during Servicing or Dismantling of Motor Vehicle Air Conditioning Systems	3.3
H-6	High GWP Reductions from Stationary Sources • High GWP Stationary Equipment Refrigerant Management Program: o Refrigerant Tracking/Reporting/Repair Deposit Program o Specifications for Commercial and Industrial Refrigeration Systems • Foam Recovery and Destruction Program • SF_6 Leak Reduction and Recycling in Electrical Applications • Alternative Suppressants in Fire Protection Systems • Residential Refrigeration Early Retirement Program	10.9
H-7	Mitigation Fee on High GWP Gases[42]	5
	Total	**20.2**

[42] The 5 $MMTCO_2E$ reduction is an estimate of what might occur with a fee in place. Additional emissions reductions from a fee would be expected as resulting revenues are used in mitigation programs. Using the funds to mitigate greenhouse gas emissions could substantially increase the emissions reductions from this measure.

15. Recycling and Waste

Reduce methane emissions at landfills. Increase waste diversion, composting, and commercial recycling. Move toward zero-waste.

California has a long track record of reducing greenhouse gas emissions by turning waste into resources, exemplified by the waste diversion rate from landfills of 54 percent (which exceeds the current 50 percent mandate) resulting from recovery of recyclable materials. Re-introducing recyclables with intrinsic energy value back into the manufacturing process reduces greenhouse gas emissions from multiple phases of product production including extraction of raw materials, preprocessing and manufacturing. Additionally, by recovering organic materials from the waste stream, and having a vibrant compost industry, there is an opportunity to further reduce greenhouse gas emissions through the indirect benefits associated with the reduced need for water and fertilizer for California's Agricultural sector. Incentives may also be an effective way to secure greenhouse gas emissions reductions in this sector. Table 20 summarizes the emissions reductions from Recycling and Waste sector.

Reduction in Landfill Methane

Methane emissions from landfills, generated when wastes decompose, account for one percent of California's greenhouse gas emissions. Greenhouse gas emissions can be substantially reduced by properly managing all materials to minimize the generation of waste, maximize the diversion from landfills, and manage them to their highest and best use. Capturing landfill methane results in greenhouse gas benefits, as well as reductions in other air pollutants such as volatile organic compounds. ARB is working closely with the California Integrated Waste Management Board (CIWMB) to develop a Discrete Early Action measure for landfill methane control that will be presented to ARB in January.

CIWMB is also pursuing efforts to reduce methane emissions by diverting organics from landfills, and to promote best management practices at smaller uncontrolled landfills. Landfill gas may also provide a viable source of liquefied natural gas (LNG) vehicle fuel. Reductions from these types of projects would be accounted for in the Transportation sector.

High Recycling / Zero Waste

This measure reduces greenhouse gas emissions primarily by reducing the substantial energy use associated with the acquisition of raw materials in the manufacturing stage of a product's life-cycle. As virgin raw materials are replaced with recyclables, a large reduction in energy consumption should be realized. Implementing programs with a systems approach that focus on consumer demand, manufacturing, and movement of products will result in the reduction of greenhouse gas emissions and other co-benefits. Reducing waste and materials at the source of generation, increased use of compost to benefit soils, coupled with increased recycling – especially in the commercial sector – and Extended Producer Responsibility (EPR) plus Environmentally Preferable Purchasing (EPP) also have the potential to reduce emissions, both in-state and within the connected global economy. This measure could also assist in meeting the 33 percent renewables energy goal through deployment of anaerobic digestion for production of fuels/energy.

As noted by ETAAC, recycling in the commercial sector could be substantially increased. This could be implemented, for example, through voluntary or mandatory programs, including protocols, enhanced partnerships with local governments, and provision of appropriate financial incentives. ARB will work with CIWMB to develop and implement these types of programs. ARB will also work with CIWMB, the California Department of Food and Agriculture, the Department of Transportation, and others to provide direct incentives for the use of compost in agriculture and landscaping. Further, CIWMB will explore the use of incentives for all Recycling and Waste Management measures, including for commercial recycling and for local jurisdictions to encourage the collection of residentially and commercially-generated food scraps for composting and in-vessel anaerobic digestion.

Table 20: Recycling and Waste Sector Recommendation - Landfill Methane Capture and High Recycling/Zero Waste
($MMTCO_2E$ in 2020)

Measure No.	Measure Description	Reductions
RW-1	Landfill Methane Control (Discrete Early Action)	1
RW-2	Additional Reductions in Landfill Methane • Increase the Efficiency of Landfill Methane Capture	TBD
RW-3	High Recycling/Zero Waste • Commercial Recycling • Increase Production and Markets for Compost • Anaerobic Digestion • Extended Producer Responsibility • Environmentally Preferable Purchasing	9
	Total	**10**[(43)]

16. Sustainable Forests

Preserve forest sequestration and encourage the use of forest biomass for sustainable energy generation.

The 2020 Proposed Scoping Plan target for California's forest sector is to maintain the current 5 $MMTCO_2E$ of sequestration through sustainable management practices, including reducing the risk of catastrophic wildfire, and the avoidance or mitigation of land-use changes that reduce carbon storage. California's Board of Forestry and

[43] Reductions from RW-2 and RW-3 are not counted toward the AB 32 goal. ARB is continuing to work with CIWMB to quantify these emissions and determine what portion of the reductions can be credited to meeting the AB 32 2020 goal. These measures may provide greater emissions reductions than estimated.

Fire Protection has the existing authority to provide for sustainable management practices, and will, at a minimum, work to maintain current carbon sequestration levels. The Resources Agency and its departments will also have an important role to play in implementing this measure.

In addition, the Resources Agency is supporting voluntary actions, including expenditure of public funds for projects focused largely on conserving biodiversity, providing recreation, promoting sustainable forest management and other projects that also provide carbon sequestration benefits. The federal government must also use its regulatory authority to, at a minimum, maintain current carbon sequestration levels for land under its jurisdiction in California.

Forests in California are now a carbon sink. This means that atmospheric removal of carbon through sequestration is greater than atmospheric emissions from processes like fire and decomposition of wood. However, several factors, such as wildfires and forest land conversion, may cause a decline in the carbon sink. The 2020 target would provide a mechanism to help ensure that current carbon stocks are, at a minimum, maintained and do not diminish over time. The 5 $MMTCO_2E$ emission reduction target is set equal to the magnitude of the current estimate of net emissions from California's forest sector. As technical data improve, the target can be recalibrated to reflect new information.

California's forests will play an even greater role in reducing carbon emissions for the 2050 greenhouse gas emissions reduction goals. Forests are unique in that planting trees today will maximize their sequestration capacity in 20 to 50 years. As a result, near-term investments in activities such as planting trees will help us reach our 2020 target, but will also play a greater role in reaching our 2050 goals.

Monitoring carbon sequestered on forest lands will be necessary to implement the target. The Board of Forestry and Fire Protection, working with the Resources Agency, the Department of Forestry and Fire Protection and ARB would be tasked with developing a monitoring program, improving greenhouse gas inventories, and determining what actions are needed to meet the 2020 target for the Forest sector. Future climate impacts will exacerbate existing wildfire and insect disturbances in the Forest sector. These disturbances will create new uncertainties in reducing emissions and maintaining sequestration levels over the long-term, requiring more creative strategies for adapting to these changes. In the short term, focusing on sustainable management practices and land-use issues is a practical approach for moving forward.

Future land use decisions will play a role in reaching our greenhouse gas emissions reduction goals for all sectors. Loss of forest land to development increases greenhouse gas emissions levels because less carbon is sequestered. Avoiding or mitigating such conversions will support efforts to meet the 2020 goal. When significant changes occur, the California Environmental Quality Act is a mechanism providing for assessment and mitigation of greenhouse gas emissions.

Going forward there are a number of forestry-related strategies that can play an important role in California's greenhouse gas emissions reduction efforts. Biomass resources from forest residue will factor into the expansion of renewable energy sources (this is currently accounted for in the Energy sector). Similarly, no reductions are yet attributed to future actions to reduce wildfire risk, but that accounting will be done following implementation. Additionally, public investments to purchase and preserve forests and woodlands would also provide greenhouse gas emission reductions that will be accounted for as projects are funded and urban forest projects can also provide the dual benefit of carbon sequestration and shading to reduce air conditioning load.

Furthermore, the Forest sector currently functions as a source of voluntary reductions that would not otherwise occur and this role could expand even further in the future. ARB has already adopted a methodology to quantify reductions from forest projects, and recently adopted additional quantification methodologies. Table 21 summarizes the emission reductions from the forest measure.

Table 21: Sustainable Forests Recommendation
($MMTCO_2E$ in 2020)

Measure No.	Measure Description	Reductions
F-1	Sustainable Forest Target	5
	Total	**5**

17. Water

Continue efficiency programs and use cleaner energy sources to move and treat water.

Water use requires significant amounts of energy. Approximately one-fifth of the electricity and one-third of the non-power plant natural gas consumed in the state are associated with water delivery, treatment and use. Although State, federal, and local water projects have allowed the state to grow and meet its water demands, greenhouse gas emissions can be reduced if we can move, treat, and use water more efficiently. As is the case with energy efficiency, California has a long history of advancing water efficiency and conservation programs. Without this ongoing, critical work, baseline or business-as-usual greenhouse gas emissions associated with water use would be much higher than is currently the case.

Six greenhouse gas emission reduction measures are proposed for the Water sector, and are shown in Table 21. Three of the measures target reducing energy requirements associated with providing reliable water supplies and two measures are aimed at reducing the amount of non-renewable electricity associated with conveying and treating water. The final measure focuses on providing sustainable funding for implementing these actions. The greenhouse gas emission reductions from these measures are indirectly realized through reduced energy requirements and are accounted for in the Electricity and Natural Gas sector.

In addition, a mechanism to make allowances available in a cap-and-trade program could be used to provide additional incentives for local governments, water suppliers, and third party providers to bundle water and energy efficiency improvements. This type of allowance set-aside will be evaluated during the rulemaking for the cap-and-trade program.

ARB recommends a public goods charge for funding investments in water management actions that improve water and energy efficiency and reduce GHG emissions. As noted by the Economic and Technology Advancements Advisory Committee, a public goods charge on water can be collected on water bills and then used to fund end-use water efficiency improvements, system-wide efficiency projects, water recycling, and other actions that improve water and energy efficiency and reduce GHG emissions. Depending on how the fee schedule is developed in a subsequent rulemaking process, a public goods charge could generate $100 million to $500 million annually. These actions would also have the co-benefit of improving water quality and water supply reliability for customers.

Table 22: Water Recommendation
($MMTCO_2E$ in 2020)

Measure No.	Measure Description	Reductions
W-1	Water Use Efficiency	1.4
W-2	Water Recycling	0.3

W-6	Public Goods Charge	TBD
	Total	**4.8**[(44)]

18. Agriculture

In the near-term, encourage investment in manure digesters and at the five-year Scoping Plan update determine if the program should be made mandatory by 2020.

Encouraging the capture of methane through use of manure digester systems at dairies can provide emission reductions on a voluntary basis. This measure is also a

[44] Greenhouse gas emission reductions from the water sector are not currently counted toward the 2020 goal. ARB anticipates that a portion of these reductions will be additional to identified reductions in the Electricity sector and is working with the appropriate agencies to refine the electricity/water emissions inventory.

renewable energy strategy to promote the use of captured gas for fuels or power production. Initially, economic incentives such as marketable emission reduction credits, favorable utility contracts, or renewable energy incentives will be needed. Quantified reductions for this measure (shown in Table 23) are not included in the sum of statewide reductions shown in Table 2 since the initial approach is voluntary. ARB and the California Climate Action Registry worked together on a manure digester protocol to establish methods for quantifying greenhouse gas emissions reductions from individual projects; the Board adopted this protocol in September 2008. The voluntary approach will be re-assessed at the five-year update of the Scoping Plan to determine if the program should become mandatory for large dairies by 2020.

Nitrogen fertilizer, which produces N_2O emissions, is the other significant source of greenhouse gases in the Agricultural sector. ARB has begun a research program to better understand the variables affecting fertilizer N_2O emissions (Phase 1), and based on the findings, will explore opportunities for emission reductions (Phase 2).

There may be significant potential for additional voluntary reductions in the agricultural sector through strategies, such as those recommended by ETAAC. These opportunities include increases in fuel efficiency of on-farm equipment, water use efficiency, and biomass utilization for fuels and power production.

Increasing carbon sequestration, including on working rangelands, hardwood and riparian woodland reforestation, also hold potential as a greenhouse gas strategies. As we evaluate the role that this sector can play in California's emissions reduction efforts, we will explore the feasibility of developing sound quantification protocols so that these and other related strategies may be employed in the future.

Table 23: Agriculture Recommendation
($MMTCO_2E$ in 2020)

Measure No.	Measure Description	Reductions
A-1	Methane Capture at Large Dairies[45]	1.0
	Total	**1.0**

D. Voluntary Early Actions and Reductions

Many individual activities that are not currently addressed under regulatory approaches can nevertheless result in cost-effective, real, additional, and verifiable greenhouse gas emissions reductions that will help California meet its 2020 target. Ensuring that appropriate credit is available to these types of emissions reduction projects will also help jump-start a new wave of technologies that will feature prominently in California and the world's long-term efforts

[45] Because the emission reductions from this measure are not required, they are not counted in the total.

to combat climate change. ARB will pursue several approaches that will recognize and reward these types of projects.

1. Voluntary Early Action

ARB is required to design regulations to encourage early action to reduce greenhouse gas emissions, and to provide appropriate recognition or credit for that action. (HSC §38562(b)(1) and (3)) Recognizing and rewarding greenhouse gas emissions reductions that occur prior to the full implementation of the AB 32 program can set the stage for innovation by incentivizing the development and employment of new clean technologies and by generating economic and environmental benefits for California.

In February 2008, ARB adopted a policy statement encouraging the early reductions of greenhouse gas emissions.[46] The policy statement describes a process for interested parties to submit proposed emission quantification methodologies for voluntary greenhouse gas emissions reductions to ARB for review. The intent is to provide a rapid assessment of methodologies for evaluating potential greenhouse gas emissions reduction projects to encourage early actions. Where appropriate, ARB will issue Executive Orders to confirm the technical soundness of the methodologies, and the methodology would be available for use by other parties to demonstrate the creation of voluntary early reductions. ARB is currently in the process of evaluating a number of submitted project methodologies.

ARB will provide appropriate credit for voluntary early reductions that can be adequately quantified and verified through three primary means. First, within the cap-and-trade program, ARB would set aside a certain number of allowances from the first compliance period to use to reward voluntary reductions that occur before 2012. In addition, ARB will assure that the allocation process in the first compliance period does not disadvantage facilities that have made reductions after AB 32 went into effect at the start of 2007 and before 2012.[47] The third approach will be to design other regulations, to the extent feasible, to recognize and reward early action. These approaches are discussed in more detail in Appendix C.

2. Voluntary Reductions

Emissions reduction projects that are not otherwise regulated, covered under an emissions cap, or undertaken as a result of government incentive programs can generate "offsets." These are verifiable reductions whose ownership can be

---

[46]Board Meeting Agenda. California Air Resources Board. February 28, 2008. http://www.arb.ca.gov/board/ma/2008/ma022808.htm (accessed October 12, 2008)

[47] ARB will evaluate whether some reductions that occurred prior to AB 32 going into effect on January 1, 2007, should also receive credit under these rules. For example, many facilities in California registered with the California Climate Action Registry after its creation in 2002 to document early actions to reduce emissions by having a record of entities profiles and baselines. ARB will evaluate what reductions made prior to 2007 should be eligible for credit from the allowance set-aside as part of the cap-and-trade program rulemaking.

transferred to others. Voluntary offset markets have recently flourished as a way for companies and individuals to offset their own emissions by purchasing reductions outside of their own operations. These sorts of voluntary efforts to reduce greenhouse gas emissions can play an important role in helping the State meet its overall greenhouse gas reduction goals.

ARB will adopt methodologies for quantifying voluntary reductions. (HSC §38571) The Board adopted a methodology for forest projects in October 2007, and for local government operations, urban forestry, and manure digesters in September 2008. The recognition of voluntary reduction or offset methodologies does not in any way guarantee that these offsets can be used for other compliance purposes. The Board would need to adopt regulations to verify and enforce reductions achieved under these or other approved methodologies before they could be used for compliance purposes. (HSC §38571)

Allowance set-asides, in addition to being used to potentially reward voluntary early actions by facilities that will be included in the cap-and-trade program, could also be used to reward voluntary early action at other facilities not covered by the cap. An early action allowance set-aside could be utilized both by entities that are covered by the cap, and by those who develop emissions reducing projects outside of the cap, or purchase the reductions associated with those projects, and have not sold or used them. Additional discussion of voluntary offsets is included in Appendix C.

E. Use of Allowances and Revenues

Revenues may be generated from the implementation of various proposed components of the Scoping Plan, including by the use of auctions within a cap-and-trade system or through the imposition of more targeted measures, such as a public goods charge on water. These revenues could be used to support AB 32 requirements for greenhouse gas emissions reductions and associated socio-economic considerations. This section summarizes some of the recommendations and ideas that ARB has received to date. As discussed in the description of the cap-and-trade measure above, ARB will seek input from a broad range of experts in an open public process regarding the options for allocation and revenue use under consideration.

The Economic and Technology Advancement Advisory Committee (ETAAC) recommended the creation of a California Carbon Trust as a possible mechanism for using revenues generated by the program, leveraged with private funds, to further the overall program goals. ETAAC's recommendation is roughly based on the United Kingdom Carbon Trust. The United Kingdom program was established with public funds, but now functions as a stand-alone corporation, providing management and consulting services to corporations and small and medium businesses on reducing greenhouse gas emissions. It also funds innovations in carbon reduction technologies. ETAAC recommended the creation of a similar organization that would use revenue from the sale of carbon allowances or from carbon fees to:

- Fund research, development and demonstration projects,
- Help bring promising and high potential technologies through the often challenging early stages of development and get them to market,
- Manage the early carbon market and mitigate price volatility, purchasing credits and selling them or retiring them as needed,
- Dedicate resources to fund projects to achieve AB 32 Environmental Justice goals, or
- Support a green technology workforce training program.

The most appropriate use for some of the allowances and revenue generated under AB 32 may be to retain it within or return it to the sector from which it was generated. For example, CEC and CPUC specifically recommended that significant portions of the revenue generated from the electricity sector under a cap-and-trade program be used for the benefit of that sector to support investments in renewable energy, efficiency, new energy technology, infrastructure, customer utility bill relief, and other similar programs. In the case of more targeted revenues from a public goods charge, the intent would be to use the funds for program purposes within the sector in which it was raised, for example in the water sector. ARB will seek input from a broad range of experts in an open public process, and will work with other agencies, the WCI partner jurisdictions, and stakeholders to consider the options for use of revenues from the AB 32 program.

Possible uses of allowances and of the revenue generated under the program include:

- **Reducing costs of emissions reductions or achieving additional reductions –** Funding energy efficiency and renewable resource development could lower overall costs to consumers and companies, and provide the opportunity to achieve greater emissions reductions than would otherwise be possible. Program revenues could be used to fund programs directly, or create financial incentives for others.
- **Achieving environmental co-benefits –** Criteria and toxic air pollutants create health risks, and some communities bear a disproportionate burden from air pollution. Revenues could be used to enhance greenhouse gas emission reductions that also provide reductions in air and other pollutants that affect public health.
- **Incentives to local governments –** Funding or other incentives to local governments for well-designed land-use planning and infrastructure projects could lead to shorter commutes and encourage walking, bicycling and the use of public transit. Funding of other incentives for local governments could also be used to increase recycling, composting, and to generating renewable energy from anaerobic digestion.
- **Consumer rebates –** Utilities and other businesses could use revenues to support and increase rebate programs to customers to offset some of the cost associated with increased investments in renewable resources and to encourage increased energy efficiency.

- **Direct refund to consumers –** Revenue from the program could be recycled directly back to consumers in a variety of forms including per capita dividends, earned income tax credits, or other mechanisms.
- **Climate change adaptation programs –** Climate change will impact natural and human environments. Program revenues could be used to help the state adapt to the effects of climate change which will be detailed in the State's Climate Adaptation Strategy being prepared by the Resources Agency to be completed in early 2009.
- **Subsidies –** Revenues could be used to reduce immediate cost impacts to covered industries required to make substantial upfront capital investments to reduce greenhouse gas emissions.
- **RD&D funding –** Revenues could be used to support research, development, and deployment of green technologies.
- **Worker transition assistance –** Regulating greenhouse gas emissions will probably shift economic growth to some sectors and green technologies and away from higher carbon intensity industries. Worker training programs could help the California labor force be competitive in these new industries.
- **Administration of a greenhouse gas program –** A portion of revenues could be used to underwrite the State's AB 32 programs and operating costs.
- **Direct emission reductions –** Revenues could be used to purchase greenhouse gas reductions for the sole purpose of retirement, providing direct additional greenhouse gas emission reductions. Potential projects, such as afforestation and reforestation, would both sequester CO_2 and provide other environmental benefits.

Many of the potential uses of revenue would help ARB implement the community benefit section of the AB 32 (HSC §38565) which directs the Board, where applicable and to the extent feasible, to ensure that the greenhouse gas emissions reduction program directs public and private investment toward the most disadvantaged communities in California.

III. EVALUATIONS

The primary purpose of the Scoping Plan is to develop a set of measures that will provide the maximum technologically feasible and cost-effective greenhouse gas emission reductions. In developing this Plan, ARB evaluated the effect of these measures on California's economy, environment, and public health. This Chapter outlines these analyses.

ARB conducted broad evaluations of the potential impacts of the Scoping Plan, and will conduct more specific evaluations during regulatory development (HSC §38561(d), and HSC §38562(b)). Prior to inclusion of market-based compliance mechanisms in a regulation, to the extent feasible, the Board will consider direct, indirect and cumulative emission impacts, and localized impacts in communities that are already adversely impacted by air pollution (HSC §38570(b)).

Based on the evaluation of the recommendations included in this Proposed Plan, implementing AB 32 is expected to have an overall positive effect on the economy. In addition, implementation of the measures in the Recommended Actions section (Chapter II) will reduce statewide oxides of nitrogen (NOx), volatile organic compounds (VOC) and atmospheric particulate matter (PM) emissions primarily due to reduced fuel consumption, with resulting public health benefits. ARB will also work at the measure-specific level to further maximize the public health benefits that can accompany implementation of greenhouse gas emissions reduction strategies. The following sections provide a summary of the ARB evaluations of the recommended measures included in this Proposed Scoping Plan. More detailed information on the evaluations and their results are provided in Appendices G and H.

A. Economic Modeling

To evaluate the economic impacts of the Scoping Plan, ARB compared estimated economic activity under a business-as usual (BAU) case to the results obtained when actions recommended in this Plan are implemented. The BAU case is briefly described below. The estimated costs and savings used as model inputs for individual measures are outlined in Appendix G, and additional documentation on the calculation of those costs and savings is provided in Appendix I. All dollar estimates are in 2007 dollars.

Under the BAU case, Gross State Product (GSP) in California is projected to increase from $1.8 trillion in 2007 to almost $2.6 trillion in 2020. The results of our economic analysis indicate that implementation of the Scoping Plan will have an overall positive net economic benefit for the state. Positive impacts are anticipated primarily because the investments motivated by several measures result in substantial energy savings that more than pay back the cost of the investments at expected future energy prices.

The business-as-usual case is a representation of what the State of the California economy will be in the year 2020 assuming that none of the measures recommended in the Scoping Plan are implemented. While a number of the measures in the plan will be implemented as the result of existing federal or State policies and do not require additional regulatory action resulting from the implementation of AB 32, they are not included in the BAU case to ensure that the economic impacts of all of the measures in the Scoping Plan are fully assessed.

The BAU case is constructed using forecasts from the California Department of Finance, the California Energy Commission, and other sources, and is described in more detail in Appendix G. ARB used a conservative estimate of future petroleum price in this analysis, $89 per barrel of oil in 2020. Aspects of the BAU case are subject to uncertainty, for example, the possibility that future energy prices could deviate from those that are included in the BAU case.

1. Macro-economic Modeling Results

Table 24 summarizes the key findings from the economic modeling. Gross State Product, personal income and employment are shown for 2007 and for two cases for 2020, the BAU case and for implementation of the Proposed Scoping Plan. For both the BAU case and the Scoping Plan case, Gross State Product increases by almost $800 billion between 2007 and 2020, personal income grows by 2.8 percent per year from $1.5 trillion in 2007 to $2.1 trillion in 2020, and employment grows by 0.9 percent per year from 16.4 million jobs in 2007 to 18.4 million (BAU) or 18.5 million (Scoping Plan) in 2020. The results consistently show that implementing the Scoping Plan will not only significantly reduce California's greenhouse gas emissions, but will also have a net positive effect on California's economic growth through 2020.

Table 24: Summary of Key Economic Findings from Modeling the Scoping Plan Using E-DRAM

Economic Indicator	2007	Business-as-Usual*		Scoping Plan		
		2020	Average Annual Growth	2020	Change from BAU	Average Annual Growth
Gross State Product ($Billion)	1,811	2,586	2.8%	2,593	0.3%	2.8%
Personal Income ($Billion)	1,464	2,093	2.8%	2,109	0.8%	2.8%
Employment (Million Jobs)	16.41	18.41	0.9%	18.53	0.7%	0.9%
Emissions ($MMTCO_2E$)	500**	596	1.4%**	422	-28%	-1.2%**
Carbon Prices (Dollars)	-	-	-	10.00	NA	-

* Business-as-usual is a forecast of the California economy in 2020 without implementation of any of the measures identified in the Proposed Scoping Plan.

** Approximate value. ARB is in currently estimating greenhouse gas emissions for 2007.

The macroeconomic modeling results presented here understate the benefits of market-based policies, including the cap-and-trade program. Consequently, our estimate of the economic impact of implementing the Scoping Plan understates the positive impact on the California economy. Nonetheless, using the current best estimates of the costs and savings of the measures, which are documented in Appendix I, the models demonstrate that implementing the Plan will have a positive effect on California's economy.

The modeling results reflect a carbon price for the cap-and-trade program of $10 per-ton. It is important to note that the $10 per-ton figure does not reflect the average cost of reductions; rather it is the *maximum* price at which reductions to achieve the cap are pursued based on the marketing program.

The positive impacts are largely attributable to savings that result from reductions in expenditures on energy. These savings translate into increased consumer spending on goods and services other than energy. Many of the measures entail more efficient use of energy in the economy, with savings that exceed their costs. In this way, investment in energy efficiency results in money pumped back into local economies. Table 25 summarizes the energy savings that are projected from implementation of the Scoping Plan. These savings are estimated to exceed $20 billion annually by 2020.

Table 25: Fuels and Electricity Saved in 2020 from Implementation of the Scoping Plan

	Gasoline	Diesel	Electricity	Natural Gas*
Use Avoided**	4,600 million gallons	670 million gallons	74,000 GWh	3,400 million therms
Value of Avoided Fuel Use (Million $2007)	$17,000	$2,500	$6,400***	$2,700
Percent Reduction from BAU	25%	17%	22%****	24%

* Not including natural gas for electric generation.

** These estimates are based on reduced use of these fuels due to increased efficiencies, reduced vehicle miles travelled, etc. Changes to the fuel mix, such as those called for under the RPS or the LCFS, are not included here. These estimates are not the same as the estimates of reduced fuel consumption used in the public health analysis.

*** Based on estimated avoided cost based on average base-load electricity, including generation, transmission and distribution.

**** This is as a percentage of BAU total California electricity consumption in 2020.

2. Impact on Specific Business Sectors

As indicated in Table 26 and Table 27, the effects of the Plan are not uniform across sectors. Implementation of the Scoping Plan would have the strongest positive impact on output and employment for the agriculture, forestry and fishing sector, the finance, insurance and real estate sector, and the mining sector. Similar to the statewide economic impacts projected by the model, however, these results also indicate that relative to the business-as-usual case, the impacts due to implementation of the Plan change current growth projections for most sectors by only very small amounts.

Table 26 and Table 27 also show that a decrease in output is projected for the utility and retail trade sectors as compared to the business-as-usual case, and a decrease in employment is projected for the utility sector. In the utility sector, the modeling indicates that implementation of the Scoping Plan would significantly reduce the need for additional power generation and natural gas consumption, which subsequently reduces the growth in output for this sector. This results in a reduction from business-as-usual for economic output and employment of approximately 17 and 15 percent respectively in 2020. The primary reason for these projections is the implementation of efficiency measures and programs for both consumers and producers. While increasing spending on efficiency and renewable energy is expected to increase employment, many of the resulting jobs will not appear in the utility sector.

The retail trade sector, which is projected to grow by nearly 50 percent in both the business-as-usual and the Scoping Plan case, is also projected to experience a slight net decline in output relative to business-as-usual. Since gasoline is considered a consumer retail purchase under this model, the reduced growth is mostly due to the decrease of approximately $19 billion in retail transportation fuel purchases, which is largely offset by the positive $14 billion increase in spending at other retail enterprises.

Table 26: Summary of Economic Output by Sector from Modeling the Scoping Plan Using E-DRAM

Sector	Output ($Billions)			
	2007	Business-as-Usual	Scoping Plan	Percent Change from BAU

Total	**16,352**	**18,405**	**18,528**	**0.6%**

3. Household Impacts

Implementation of the Scoping Plan will provide low- and middle-income households savings on the order of a few hundred dollars per year in 2020 compared to the business-as-usual case, primarily as a result of increased energy efficiencies.

Low-Income Households: Based on current U.S. Department of Health and Human Services poverty guidelines, we evaluated the projected impacts of the plan on households with earnings at or below both 100 and 200 percent of the poverty guidelines. For all households, including those with incomes at 100 percent and 200 percent of the poverty level, implementation of the Scoping Plan produces a slight increase in per-capita income relative to the business-as-usual case.

At the same time, the analysis projects an increase of approximately 50,000 jobs available for lower-income workers[48] relative to business-as-usual as a result of implementing the Plan. The largest employment gains come in the retail, food service, agriculture, and health care fields. A decline in such jobs is projected in the retail gasoline sector due to the overall projected decrease in output from this sector. This decline, however, is more than offset by the increases experienced in other areas.

Another important factor to consider when analyzing the impact of the Scoping Plan on households is how it will affect household expenditures. As indicated in Table 28, analysis based on the modeling projections estimates a savings (i.e., reduced expenditures) of around $400 per household in 2020 for low-income households under both federal poverty guideline definitions. These savings are driven primarily by the implementation of the clean car standards and energy efficiency measures in the Scoping Plan that over time are projected to outweigh potential increases in electricity and natural gas prices that may occur. As the measures in the Scoping Plan are implemented, ARB will work to ensure that the program is structured so that low income households can fully participate in and benefit from the full range of energy efficiency measures. Many of California's energy efficiency efforts are targeted specifically at low income populations, and the CPUC's Long Term Strategic Plan for energy efficiency has redoubled its objective for the delivery of energy efficiency measures to low income populations. Additional information regarding the data in Table 28 can be found in Appendix G.

[48] Low-income jobs are defined as those with a median hourly wage below $15 per hour (2007 dollars) based on wage data and staffing pattern projections from the California Employment Development Department. The shares of low-wage occupations for each industry are then applied to the corresponding E-DRAM sector employment projections.

Table 28: Impact of Implementation of the Scoping Plan on Total Estimated Household Savings in 2020 (2007 $)

Income at 100% of Poverty Guideline	Income at 200% of Poverty Guideline	Middle Income*	High Income**	All Households***
$400	$400	$500	$500	$500

* All households between 200% and 400% of the poverty guidelines.

** All households above 400% of the poverty guidelines.

*** Average of households of all income levels.

The analysis indicates that implementation of the Scoping Plan is likely to result in small savings for most Californians, with little difference across income levels. Largely due to increased efficiencies, low-income households are projected to be slightly better off from an economic perspective in 2020 as a result of implementing AB 32.

Middle-Income Households: Implementation of the plan produces a small increase in household income across all income levels, including middle-income households, relative to the business-as-usual case.[49] In terms of how jobs for middle-income households[50] would be impacted, the modeling indicates a slight overall increase of almost 40,000 in 2020.

As shown in Table 28, the analysis projects a net-savings in annual household expenditures of about $500 in 2020 for middle-income households. These savings are driven by the emergence of greater energy efficiencies that will be implemented as a result of the plan.

4. WCI Economic Analysis

The Proposed Scoping Plan recommends that California develop a cap-and-trade program that links to the broader regional market being developed by the Western Climate Initiative (WCI). In order to examine the economic impacts of WCI program design options, WCI Partner jurisdictions contracted with ICF International and Systematic Solutions, Inc. (SSI) to perform economic analyses using ENERGY 2020, a multi-region, multi-sector energy model. The WCI economic modeling results are reported in full in Appendix D and are discussed in the Background Report on the Design Recommendations for the WCI Regional Cap-and-Trade Program, also included in Appendix D.

To help inform the program design process, the WCI analysis examined the implications of key design decisions, including: program scope, allowance banking,

[49] For purposes of our analysis we define "middle-income" households as those earning between 200% and 400% of the federal poverty guidelines.

[50] Hourly wage between $15 and $30 per hour.

and the use of offsets. Due to time and resource constraints, the modeling was limited to the eight WCI Partner jurisdictions in the Western Electric Coordinating Council (WECC) area, thereby excluding from the analysis three Canadian provinces, Manitoba, Quebec, and Ontario. Future analyses are planned that will integrate these provinces so that a full assessment of the WCI Partner jurisdictions can be performed.

The WCI modeling work is not directly comparable to the ARB results reported here. The WCI analysis relies on a more aggregated set of greenhouse gas emissions reduction measures rather than the specific individual policies recommended in the Proposed Scoping Plan; it uses somewhat different assumptions regarding what measures are included in the "business-as-usual" case, and it models the entire WECC rather than California. Nevertheless, the results of the WCI modeling provide useful insight into the economic impact of greenhouse gas emissions reduction policies.

Consistent with the conclusions of the ARB evaluation, overall the WCI analysis found that the WCI Partner jurisdictions can meet the regional goal of reducing emissions to 15 percent below 2005 levels by 2020 (equivalent to the AB 32 2020 target) with small overall savings due to reduced energy expenditures exceeding the direct costs of greenhouse gas emissions reductions. The savings are focused primarily in the residential and commercial sectors, where energy efficiency programs and vehicle standards are expected to have their most significant impacts. Energy-intensive industrial sectors are estimated to have small net costs overall (less than 0.5 percent of output).

The WCI analysis does not examine the potential macroeconomic impacts of the costs and savings estimated with ENERGY 2020. The WCI Partner jurisdictions are planning to continue the analysis so that macroeconomic impacts, such as income, employment, and output, can be assessed. Once completed, the macroeconomic impacts can be compared to previous studies of cap-and-trade programs considered in the United States and Canada.

B. Green Technology

The development of green technologies and a trained workforce equipped to design, develop and deploy them will be key to the success of California's long-term efforts to combat global warming. Bold, long-range environmental policies help drive innovation and investment in emission-reducing products and services in part by attracting private capital. Typically, the private sector under invests in research and development for products that yield public benefits. However, when environmental policy is properly designed and sufficiently robust to support a market for such products, private capital is attracted to green technology development as it is to any strategic growth opportunity.

California's leadership in environmental and energy efficiency policy has helped attract an increasing share of venture capital investment in green technologies. According to statistics from PricewaterhouseCoopers and the National Venture Capital Association, California's share of U.S. venture capital investment in innovative energy technologies increased dramatically from 1995 to 2007 (see Figure 5 below).[51] The same period saw a stream of pioneering environmental policy initiatives, including energy efficiency codes for buildings and appliances, a renewables portfolio standard for electricity generation, climate change emissions standards for light-duty automobiles and, most recently, AB 32. Flows of venture capital into California are escalating as a direct result of the focus on reductions of greenhouse gas emissions. As mentioned above, California captured the largest single portion of global venture capital investment ($800 million out a total of two billion dollars) during the second quarter of 2008.

investments in comparable conventional technologies.[53] Venture capitalists estimate that each $100 million in venture capital funding, over a period of two decades, helps create 2,700 jobs, $500 million in annual revenues, and many indirect jobs.[54]

Access to capital controlled by institutional investors is also enhanced by policies that encourage early adoption of green technologies. When California-based corporations use green technologies to reduce their exposure to climate change risk, institutional investors reward them by facilitating their access to capital. The Investor Network on Climate Risk – including institutional investors with more than $8 trillion of assets under management – endorsed an action plan in 2008 that calls for requiring asset managers to consider climate risks and opportunities when investing; investing in companies developing and deploying clean technologies; and expanding climate risk scrutiny by investors and analysts.[55]

Additional capital for green technologies helps drive increased employment, both indirectly, as energy savings are plowed back into other sectors of the economy, and directly, as new green products are successfully commercialized.

McKinsey & Company projects average annual returns of 17 percent on global investments in energy productivity, and estimates the global investment opportunity at $170 billion annually through 2020.[56] Meanwhile, global investment in energy efficiency and renewable energy has grown from $33 billion to more than $148 billion in the last four years. Beyond 2020, green technologies are expected to attract investment of more than $600 billion annually.[57] In short, green technology is now a *bona fide* global growth industry.

Today, green technology businesses directly employ at least 43,000 Californians, primarily in energy efficiency and energy generation, according to a 2008 study from the California Economic Strategy Panel. Green jobs are concentrated in manufacturing (41 percent), and

professional, scientific and technical services (28 percent), with median annual earnings of $35,725 and $56,754, respectively.[58] By 2030, under a moderate growth scenario, green businesses nationwide are expected to generate revenues of $2.4 trillion, (2006 dollars), and employ 21 million Americans.[59]

As a leader in green technology development and use, California has already realized substantial economic benefits from the adoption of energy efficiency policies. State energy efficiency measures have saved enough energy over the past 30 years to avoid construction of two dozen 500-megawatt power plants. Today, California's per capita electricity consumption is 40 percent below the national average, and the carbon intensity of California's economy is among the lowest in the nation.[60]

Renewable energy, such as solar, wind, biomass, geothermal, will also bring new employment opportunities to Californians while spurring economic growth. California enjoys significant comparative advantages for renewable energy: concentrated innovation resources, a large potential customer base, key natural resources such as reliable solar and wind, and supportive regulatory programs, including the California Renewables Portfolio Standard, the Million Solar Roofs Initiative, the California Global Warming Solutions Act of 2006, and the Solar Water Heating and Efficiency Act of 2007.

Other researchers have estimated that under a national scenario with 15 percent renewables penetration by 2020, California will experience a net gain in direct employment of 140,000 jobs.[61] Because investments in green technologies produce jobs at a higher rate than investments in conventional technologies, jobs losses that occur in traditional fossil fuel industries will be more than compensated for by gains in the clean energy sector.

Furthermore, if California's renewable energy suppliers field products that are sufficiently competitive to penetrate the export market, employment and earnings dividends for the state will also increase. California renewable energy industries servicing the export market can generate up to 16 times more employment than those that only manufacture for domestic

consumption, according to a study by the Research and Policy Center of Environment California.[62]

C. Cost-Effectiveness

As noted in several provisions of AB 32, cost-effectiveness is an important requirement to be considered in the design and implementation of emission reduction strategies. (See HSC §§38505, 38560, 38561, 38562.) AB 32 defines "cost-effective" or "cost-effectiveness" as "the cost per unit of reduced emissions of greenhouse gases adjusted for its global warming potential." (HSC §38505(d)) This definition specifies the metric (i.e., dollars per ton) by which the Board must express cost-effectiveness, but it does not provide criteria to assess if a regulation is or is not cost-effective. It also does not specify whether there should be a specific upper-bound dollar per ton cost that can be considered cost-effective, or how such a bound would be determined or adjusted over time. ARB has investigated different approaches that could be used to evaluate the cost-effectiveness of regulations and is recommending the following approach.

The estimated cost per ton of greenhouse gas emissions reduced by the measures recommended in this Plan ranges from $-408 (net savings) to $133, with all but one (the Renewables Portfolio Standard) costing less than $55 per ton. The RPS is being implemented for energy diversity purposes, not just greenhouse gas reductions, and the $133 per ton figure does not take these other benefits into account. Therefore, it should not be used as a reference to define the range of cost-effective greenhouse gas measures. These estimates are based on the best information available as ARB prepared this Proposed Plan. Updated estimates and greater certainty will be provided as the measures are further developed during the rulemaking process.

In the meantime, the current estimates provide a range illustrating the cost per ton of the mix of measures that collectively meet the 2020 target. This range will assist the Board in evaluating the cost-effectiveness of individual measures when considering adoption of regulations. The range of acceptable cost-effectiveness may change if effective lower-cost measures and options are identified. Because both the projections of "business-as-usual" 2020 emissions and the degree of reductions from any given measures may be greater or less than current estimates, the determination should remain flexible to accommodate a higher or lower estimate of cost-effectiveness. In addition, the approach must provide flexibility to pursue measures that simultaneously achieve policy objectives other than greenhouse gas emissions reduction (such as energy diversity).

The criteria for judging cost-effectiveness will be updated as additional technological data and strategies become available. As ARB moves from adoption of the Scoping Plan to

---

[62] Environment California Research and Policy Center. *Renewable Energy and Jobs. Employment Impacts of Developing Markets for Renewables in California*. July 2003. As cited in: Putting Renewables to Work: How Many Jobs Can the Clean Energy Industry Generate? Energy and Resources Group/Goldman School of Public Policy at University of California, Berkeley. April 13, 2004. http://rael.berkeley.edu/old-site/renewables.jobs.2006.pdf (accessed October 12, 2008)

developing specific regulations, and as regulations continue to be adopted, updated cost-effectiveness estimates will be established in a rigorous and transparent process with full stakeholder participation. As ARB progresses from proposed measures and estimated costs to actual regulations, the comparison of cost-effectiveness would move toward the well established practice of comparing the cost-effectiveness of new regulations to the cost-effectiveness of previously enacted and/or similar regulations. This approach is consistent with how cost-effectiveness is evaluated for strategies to reduce criteria and toxic pollutants.

D. Small Business Impact

Small businesses play an important role in California's economy. As required under AB 32, ARB analyzed the impact that implementation of the Scoping Plan would have on small businesses in the state. The analysis indicates that the primary impacts on small businesses as a result of AB 32 will come in the form of changes in the costs of goods and services that they procure, and in particular, changes in energy expenditures. Due to the number of measures in the plan that will deliver significantly greater energy efficiencies, our analysis projects that implementation of the plan will have a positive impact on small business in California even after taking into account the higher per-unit energy prices that are likely to occur between now and 2020. Small businesses also will benefit as a result of the robust economic growth and the increases in jobs, production, and personal income that are projected between now and 2020 as AB 32 is implemented. Additional information is provided in Appendix G.

Recent analysis from Energy and Environmental Economics, Inc. (E3) forecasts that a package of greenhouse gas emissions reduction measures similar to those recommended in this Plan would deliver a five percent decrease in electricity expenditures for the average California electricity customer relative to business-as-usual in 2020.[63] This projection is based on the assumption that increases in electricity prices will be more than offset by the continued expansion of energy efficiency measures and that more efficient technologies will be developed and implemented.[64] For purpose of this analysis, expenditures on natural gas are assumed to remain the same, balancing the projected 29 percent decrease in natural gas consumption in California with the model's projected natural gas price increase of almost 9 percent.

Based on this assessment, implementation of the Scoping Plan will likely have minor but positive impacts on small businesses in the state. These benefits are attributable primarily to the measures in the plan that will deliver significantly greater energy and fuel efficiencies. Even when higher per unit energy prices are taken into account, these efficiencies will decrease overall energy expenditures for small businesses. Additionally, as previously described, the California economy is projected to experience robust economic growth

[63] Based on their GHG Calculator, CPUC/CEC GHG Docket (CPUC Rulemaking.06.04.009, CEC Docket 07-OIIP-01), available at http://www.ethree.com/cpuc_ghg_model.html.

[64] The E3 analysis focuses on direct programmatic measures and does not include the incremental price impact of the cap-and-trade program, which will depend upon allowance price, allocation strategy, the capped sector industry response, and other program design decisions.

between now and 2020 as AB 32 is implemented. Small businesses will experience many of the benefits associated with this growth in the form of more jobs, greater production activity, and rising personal income.

The projected decrease in electricity expenditures is especially important for small businesses since they typically spend more on energy as a percentage of revenue compared to larger enterprises. For example, firms with a single employee spend approximately 3.3 percent of each sales dollar on electricity, while businesses with between ten and forty-nine employees spend around 1.2 percent. As a result, smaller businesses are likely to experience a greater relative benefit from decreased energy expenditures relative to their larger counterparts.

From the broader economic perspective, these changes will make California more competitive as a location for small business, moving it from 7th highest to 19th among all states in terms of the percentage of revenue that businesses expend on electricity.[65] As was noted above for low income households, care must be taken to ensure that the program is structured to allow small businesses to participate in and benefit from the energy efficiency measures.

While ARB's analysis indicates a positive impact on small businesses from AB 32 implementation, to ensure that these benefits are realized to the fullest potential it will take additional outreach and communication efforts on the part of ARB and many other state and local entities. There are a number of existing programs that are designed to help small businesses achieve greater efficiencies in energy use. These programs can be enhanced and expanded upon, and new programs and efforts can be developed to ensure that all small businesses in California are aware of and able to take cost-effective steps to reduce energy use and enjoy the associated economic savings. For example, as discussed more completely in Chapter IV, ARB and our partners in State government are working together to develop an on-line small business "toolkit" designed for small and medium-sized businesses to provide a one-stop shop of technical and financial information resources. As further development and implementation of the measures in the plan proceeds, we will work with other state and local partners to ensure that small businesses can both benefit from and play a role in helping to achieve our greenhouse gas emission reduction requirements.

E. Public Health/Environmental Benefits Analyses

AB 32 requires ARB to evaluate the environmental and public health impacts of the Scoping Plan. The analysis of this plan is focused primarily on the quantification of public health benefits from air quality improvements that would result from implementation. Unlike traditional pollutants and toxic emissions, global warming pollutants do not typically have localized impacts. At ambient levels, carbon dioxide, which makes up over 80 percent of global warming pollutants in California, has no direct environmental or public health consequences. Climate change caused by greenhouse gas pollutants emitted in another state

[65] Although the natural gas data is less specific, a similar scenario is expected where increased prices are typically offset by greater efficiencies for most small businesses.

or country has the same potential to damage our public health and the environment as does climate change due to pollutants emitted within California. Although this analysis does not consider the public health impacts of climate change, the potential public health impacts are great, and have been well documented elsewhere. However, many of the measures aimed at reducing global warming pollutants also provide co-benefits to public health and California's natural resources.

The environmental and cumulative impacts of the Plan are discussed in the California Environmental Quality Act (CEQA) document that is included in Appendix J. As the Scoping Plan is implemented, and specific measures are developed, ARB will conduct further CEQA analyses, including cumulative and multi-media impacts. As ARB further develops its approach for consideration of these issues in future rulemakings, and updates needed analytical tools and data sets, we will consult with outside experts and the EJAC. ARB recognizes that the adoption of the Scoping Plan will launch a variety of regulatory proceedings in many different venues. ARB will work closely with other California State agencies including: the Office of Planning and Research, Environmental Protection Agency, Resources Agency, Integrated Waste Management Board, Department of Public Health, Office of Environmental Health Hazard Assessment, State Water Resources Control Board, Department of Toxic Substances Control, Department of Water Resources, Board of Forestry, Department of Fish and Game, Public Utilities Commission, California Energy Commission, and others to identify and address potential multi-media environmental impacts early in the regulatory development process.

California's actions to reduce greenhouse gas emissions will help transition the State to new technologies, improved efficiencies, and land use patterns also necessary to meet air quality standards and other public health goals. California's challenging public health issues associated with air pollution are already the focus of comprehensive regulatory and incentive programs. These programs are reducing smog forming pollutants and toxic diesel particulate matter at a rapid pace. However, to meet increasingly stringent air quality standards and air toxics reduction goals, transformative changes are needed in the 2020 timeframe and beyond. Implementation of AB 32 will provide additional support to existing State efforts devoted to protecting and improving public health.

1. Key Air Quality-Related Public Health Benefits

The primary direct public health benefits of the Proposed Scoping Plan are reductions in smog forming emissions and toxic diesel particulate matter. The most significant reductions are of oxides of nitrogen (NOx), which forms both ozone and particulate pollution (PM2.5), and directly emitted PM2.5, which includes diesel particulate matter. The analysis focuses on PM2.5 impacts and quantifies 2020 public health benefits of this plan in terms of avoided premature deaths, hospitalizations, respiratory effects, and lost work days. Additional benefits associated with the reductions in ozone forming emissions were not quantified since statewide 2020 photochemical modeling is not available.

The estimated air quality-related public health benefits of the Proposed Scoping Plan are above and beyond the much greater benefits of California's existing programs, which are reducing air pollutant emissions every year. This continuing progress is the result of California's plans for meeting air quality standards ("State Implementation Plans" or SIPs), reducing emissions from goods movement activities, and addressing health risk from diesel particulate matter. These programs address both existing and new sources of air pollution, taking into account population and economic growth. The additional benefits of the Proposed Scoping Plan in 2020 are significant, and in the longer term, can be expected to increase with further reductions in fossil fuel combustion, the primary basis for the estimated public health benefits.

The recommended measures in the Proposed Scoping Plan that reduce smog forming ("criteria") pollutants are shown in Table 29 along with the estimated reductions. Statewide, these measures would reduce approximately 61 tons per day of NOx and 15 tons per day of PM2.5 in 2020. As shown in Table 30, this equates to an estimated air quality-related public health benefit of 400 avoided premature deaths statewide. In comparison, reductions in PM2.5 from California's existing programs and 2007 SIP measures are estimated to result in 3,700 avoided premature deaths statewide in the same timeframe.

Table 29: Statewide Criteria Pollutant Emission Reductions in 2020 from Proposed Scoping Plan Recommendation[66]

(tons per day)

Measure	NOx	PM2.5
Light-Duty Vehicle • Pavley I and Pavley II GHG Standards • Vehicle Efficiency Measures	1.6	1.4
Goods Movement Efficiency Measures	16.9	0.6
Medium and Heavy-Duty Vehicle GHG Emission Reduction • Aerodynamic Efficiency • Hybridization • Engine Efficiency	5.6	0.2
Local Government Actions and Regional Targets	8.7	1.4
Energy Efficiency and Conservation (Electricity)	7.0	4.0
Energy Efficiency and Conservation (Natural Gas)	10.4	0.8
Solar Water Heating	0.3	0.03
Million Solar Roofs	1.0	0.6
Renewables Portfolio Standard	9.8	5.6
Total	**61**	**15**

[66] Table 29 does not include the criteria pollutant co-benefits of additional greenhouse gas reductions that would be achieved from the proposed cap-and-trade regulation because we cannot predict in which sectors they would be achieved.

Table 30: Estimates of Statewide Air Quality-Related Health Benefits in 2020

Health Endpoint	Health Benefits of Existing Measures and 2007 SIP *mean*	Health Benefits of Recommendations in the Proposed Scoping Plan *mean*
Avoided Premature Death	3,700	400
Avoided Hospital Admissions for Respiratory Causes	770	84
Avoided Hospital Admissions for Cardiovascular Causes	1,400	150
Avoided Asthma and Lower Respiratory Symptoms	110,000	11,000
Avoided Acute Bronchitis	8,700	910
Avoided Work Loss Days	620,000	67,000
Avoided Minor Restricted Activity Days	3,600,000	380,000

In addition to the quantified air-quality-related health benefits, our analysis indicates that implementation of the Proposed Scoping Plan can deliver other public health benefits as well. These include potential health benefits associated with local and regional transportation-related greenhouse gas targets that can facilitate greater use of alternative modes of transportation, such as walking and bicycling. These types of moderate physical activities reduce many serious health risks including coronary heart disease, diabetes, hypertension and obesity.[67] Finally, it is important to note that the steps California is taking to address global warming, along with actions by other regions, states, and nations, will help mitigate the public health effects of heat waves, more widespread incidence of illness and disease, and other potentially severe impacts.

The measures in the Proposed Scoping Plan are designed primarily to help spur the transition to a lower carbon economy. However, in addition to improving air quality, these measures can also improve California's environmental resources, including land, water, and native species. Land resources will be affected by regional transportation-related targets leading to improved land use planning, and forest carbon sequestration targets which can result in better stewardship of California lands and reduced wildfire risk. A number of conservation measures will aid in effective management of the State's precious water resources. Demand for waste disposal and hazardous materials should decrease as measures to encourage recycling and reuse transform our wastes into fuel, energy, and other useful products are implemented. Additional analysis of the way that implementation of the Scoping Plan will impact these environmental resources will be conducted as we proceed. Many of these measures serve the dual purpose of mitigating greenhouse gas emissions and helping California adapt to the impacts of climate change.

[67] Appendix H contains a reference list of studies documenting the public health benefits of alternative transportation.

2. Approach

ARB quantified the potential reductions of NOx and PM2.5 from implementation of the Proposed Plan's recommendations, and the public health benefits associated with the resulting potential air quality improvement. These analyses compare NOx and PM2.5 emissions in 2020 with the implementation of the Scoping Plan with NOx and PM2.5 emissions in 2020 in the absence of the Scoping Plan – a "business-as-usual" scenario. The methodology used to evaluate the public health benefits of the emission reductions is similar to the methodology used in ARB's 2006 Goods Movement Emission Reduction Plan (GMERP).[68] This methodology is based on a peer-reviewed methodology developed by the U.S. Environmental Protection Agency (U.S. EPA). ARB augmented U.S. EPA's methodology by incorporating the result of new epidemiological studies relevant to California's population, including regionally specific studies, as they became available.

AB 32 directs ARB to conduct several levels of analysis as we proceed through the development and implementation of a comprehensive greenhouse gas emissions reduction strategy. As part of the Scoping Plan development, ARB is required to assess both the economic and non-economic impacts of the plan as noted above. Additionally, AB 32 requires ARB to undertake additional analysis at the time of adoption of regulations, including market-based compliance mechanisms.

Although not yet at the stage of regulatory development and adoption, in this analysis ARB conducted an evaluation of the air quality-related public health benefits associated with the Proposed Scoping Plan based on a community level emissions analysis example. As regulations that rely on market-based compliance mechanisms are further developed for consideration by the Board, more detail about the specific regulatory proposals will be developed, enabling ARB to more closely evaluate the potential for direct, indirect and cumulative impacts.

3. Existing Programs for Air Quality Improvement in California

The public health analysis of the Proposed Scoping Plan presents air-quality benefits that will occur in addition to the benefits of California's comprehensive air quality programs designed to meet health-based standards and reduce health risk from air toxics. It is also important to note that under both a "business-as-usual" scenario and under the implementation of the Proposed Scoping Plan, the population and economy of California are projected to continue to grow. New businesses and industries will continue to be sited in California, bringing both economic opportunity and potential environmental impacts. Federal, State, and local laws and regulations have established requirements to ensure that new and modified sources of pollution are carefully evaluated and that significant impacts are mitigated. Emissions from existing businesses are also tightly controlled by local air pollution control districts.

[68] Air Resources Board. Technical Supplement on Health Analysis. *Technical Supplement on Quantification of the Health Impacts and Economic Valuation of Air Pollution from Ports and Goods Movement in California.* March 2006 http://www.arb.ca.gov/planning/gmerp/gmerp.htm (accessed October 12, 2008)

Statewide programs are in place to reduce emissions from cars, trucks, and off-road equipment, along with smog check, cleaner gasoline and diesel fuels, and regulations to reduce evaporative emissions from consumer products, paints, and refueling. Additional information about the existing regulatory framework for sources of air pollution is provided in Appendix H.

It is important to evaluate the air quality and public health benefits of the Proposed Scoping Plan in the context of the State's on-going air quality improvement efforts. California's long-standing air pollution control programs have substantially improved air quality in the state and will continue to do so in the future. By 2020, these programs will deliver reductions in statewide NOx emissions of 441 tons per day and direct fine particle emission reductions of 34 tons per day. Through 2020, three key ARB efforts will deliver deep reductions in air pollutant emissions despite continuing growth:

- Diesel Risk Reduction Plan
- Goods Movement Emission Reduction Plan
- 2007 State Implementation Plan

Measures in these plans will result in the accelerated phase-in of cleaner technology for virtually all of California's diesel engine fleets including trucks, buses, construction equipment, and cargo handling equipment at ports. Adoption and implementation of these and other measures are critical to achieving clean air and public health goals statewide.

The U.S. Environmental Protection Agency has set a new, more stringent, national ambient air quality standard for ozone that will have compliance deadlines well past 2020 for the most severely impacted areas like southern California.[69] The unmitigated impacts of climate change will make it harder to meet this standard and to provide healthful air to Californians.

4. Statewide Analysis

For this evaluation, ARB examined the recommended measures to determine the potential for impacts on air, land, water, native species and biological resources, and waste and hazardous materials. Local government, State government, and green building sectors were not included in this evaluation as they represent means of implementation of the greenhouse gas emission reduction measures. As noted, the main focus of this analysis is on air quality. To the extent feasible, ARB quantified estimated emissions reductions in criteria pollutants associated with each recommended measure except cap-and-trade. Reductions in NOx and PM2.5 were used to estimate public health benefits. The estimated statewide reductions are

[69] U.S. Environmental Protection Agency. *National Ambient Air Quality Standards for Ozone. Final Rule.* 73 Federal Register 16436. March 27, 2008. http://www.epa.gov/fedrgstr/EPA-AIR/2008/March/Day-27/a5645.pdf (accessed October 12, 2008)

61 tons per day of NOx and 15 tons per day of PM2.5. Further analysis of the potential criteria pollutant benefits of a cap-and-trade program will be done as part of regulatory development.

5. Regional Assessment: South Coast Air Basin Example

In order to assess potential air quality benefits of the Proposed Scoping Plan on a regional level, ARB evaluated associated criteria pollutant reductions in the South Coast Air Basin as an example case. Existing programs will reduce current NOx emissions by almost 50 percent in 2020. With the new 2007 SIP measures, NOx emissions will be reduced almost 60 percent. Because of the large population and high pollutant concentrations in this region, greater benefits occur from each ton of pollution reduced. The estimated air quality-related public health benefits of the Proposed Scoping Plan for the South Coast region are shown in Table 31. The significant air quality-related public health benefits in this region are largely attributed to the additional reductions in PM2.5.

Table 31: Estimated Air Quality-Related Health Benefits of Existing Program, 2007 SIP, and Proposed Scoping Plan in the South Coast Air Basin, 2020

Health Impacts / Scenario	Benefits from Existing Program	Additional Benefits from 2007 SIP	Additional Co-Benefits from Proposed Scoping Plan
Premature Deaths Avoided	1,600	920	200
Hospitalizations Avoided – Respiratory	330	200	42
Hospitalizations Avoided – Cardiovascular	610	360	78
Asthma & Lower Respiratory Symptoms Avoided	46,000	28,000	5,900
Acute Bronchitis Avoided	3,800	2,300	490
Work Loss Days Avoided	270,000	160,000	35,000
Minor Restricted Activity Days Avoided	1,600,000	940,000	200,000

6. Community Level Assessment: Wilmington Example

ARB also conducted an evaluation of the potential air quality impacts of the Proposed Scoping Plan in the community of Wilmington as an illustration of the potential for localized impacts. Wilmington is in southern Los Angeles County and includes a diverse range of stationary and mobile emissions sources, including the ports of Los Angeles and Long Beach, railyards, major transportation corridors, refineries, power plants, and other industrial and commercial operations. Like the regional analysis, additional emission reductions from the 2007 SIP were estimated and show significant reductions in Wilmington by 2020 – approximately a 45 percent reduction in NOx and a 40 percent reduction in directly-emitted PM2.5. Mobile source emissions are projected to continue to be proportionately greater than stationary source emissions in 2020 even as mobile source emissions decline.

For this assessment, ARB evaluated criteria pollutant emission reductions in the Wilmington study area assuming that the source-specific quantified measures are implemented, including measures to reduce emissions from oil and gas extraction and refineries. It was further assumed that the non-source specific program elements, such as the proposed cap-and-trade program, result in a 10 percent reduction in fuel combustion by affected sources within the study area. For example, it is estimated that industrial sources would achieve greenhouse gas emission reductions through efficiency measures that reduce on site fuel use by 10 percent either in response to a cap-and-trade program, or due to the results of the facility energy efficiency audits. While it is likely that the actual onsite reductions will differ across individual facilities from the assumed uniform ten percent reduction,[70] the analysis identifies how reductions at these facilities affect the overall level of co-benefits.

The estimated NOx co-benefit of about 1.7 tons per day is small relative to the projected reductions of 24 tons per day that will occur as a result of the SIP and other measures. For example, an 8 ton per day NOx reduction is expected from cleaner port trucks. In comparison, the potential NOx benefit from a 10 percent efficiency improvement in major goods movement categories is estimated at about 1.5 tons per day. The estimated PM2.5 co-benefits, on the order of 0.12 tons per day, are also small relative to the projected reductions of 2.3 tons per day that will occur as a result of the SIP and other measures. Approximately 30 percent (0.04 ton per day) of the PM 2.5 co-benefit reduction is associated with assumed energy efficiency measures at the four large refineries in the study area, while another 30 percent would occur due to a 10 percent efficiency improvement by goods movement sources.

The co-benefit emissions reductions in the study area would produce regional air quality-related health benefits. A relatively small portion of these benefits would occur in the study area (approximately 300,000 area residents). Health benefits due to reductions in NOx are mostly at the regional levels, since NOx emissions have usually travelled some distance before they are transformed into PM via atmospheric reactions. Point source combustion PM emissions persist in the atmosphere and increase exposures both in the area where they are emitted and broadly throughout the region. Based on previous modeling studies of the impact of port and rail yard PM emissions in the South Coast Air Basin conducted by ARB, PM exposures will be reduced far beyond the study area, and a majority of the health benefits are expected to occur in areas outside of the Wilmington community.[71]

Using the previously described methodology that correlates emission reductions in the air basin with expected regional health benefits there would be an estimated

---

[70] The reductions at any one facility could be much greater or lesser than 10 percent For example, very small or no reductions might occur because available cost-effective industrial emission reductions have already been implemented at a particular site.

[71] ARB analysis indicates that about 20 percent of the health benefits would occur in the Wilmington area.

11 avoided premature deaths attributed to emission reductions that occur in Wilmington as a result of the Scoping Plan.[72]

F. Summary of Societal Benefits

AB 32 requires ARB to "consider the overall societal benefits, including reductions in other air pollutants, diversification of energy sources, and other benefits to the economy, environment, and public health" (HSC § 38562(b)(6)) when developing regulations to implement the Scoping Plan. ARB conducted an initial assessment of societal benefits associated with AB 32 implementation. This section summarizes those that have been identified during development of the Scoping Plan, including diversification of energy sources, mobility, regressivity, and job creation. More detailed economic and environment/public health analyses can be found in Appendix G and H, respectively. The impact of low income households (regressivity), impacts on small businesses, and impact on jobs are described in the Economic Analysis section and Appendix G.

1. Energy Diversification

Generally, energy-related measures in this Proposed Scoping Plan are expected to result in a transformation of the State's energy portfolio, driven primarily by the Low Carbon Fuel Standard (LCFS), which addresses transportation fuel, and the 33 percent RPS, which increases renewably-produced electricity production and distribution to households and businesses.

The LCFS aims to achieve at least a 10 percent reduction in the carbon intensity of California's transportation fuels by 2020. As the State moves toward less dependence upon one source of fuel for transportation, our economy will be less at risk from significant fluctuations in fuel prices. Measures within the Scoping Plan will force energy diversification in California toward low-carbon intensive energy sources and encourage significant growth in infrastructure, capital, and investment in biofuels.

The move toward 33 percent renewables will, by definition, increase the diversification of California's electrical supply. Increased use of wind, solar, geothermal and biomass (including from the organic fraction of municipal solid waste) generation will all add to ensuring the state has a broader portfolio of energy inputs.

Based on ARB's economic analysis, the combined energy diversification and increased energy efficiency expected from implementation of the Scoping Plan is predicted to result in: a 25 percent decrease in gasoline usage (4.6 billion gallons), a 17 percent decrease in diesel fuel use (670 million gallons), a 22 percent decrease in electricity (74,000 GWh reduction) and a 24 percent reduction in natural gas (3,400 therms).

[72] See Appendix H

The cap-and-trade program, offsets, and other measures that contain market-based features may also help diversify California's energy portfolio by incentivizing the development and deployment of clean and efficient energy generating technologies.

2. Mobility and Shifts in Land Use Patterns

Mobility is analyzed through multiple approaches in the Proposed Scoping Plan. Appendix C includes an analysis of a proposed measure for regional transportation-related greenhouse targets. Reductions in vehicle miles traveled (VMT) are expected to result from regional and local planning which target land use, building and zoning improvements.

As the Scoping Plan is implemented, measures that support shifts in land use patterns are expected to emphasize compact, low impact growth in urban areas over development in greenfields. Communities could realize benefits, such as improved access to transit, improved jobs-housing balance, preservation of open spaces and agricultural fields, and improved water quality due to decreased runoff. Local and regional strategies promoting appropriate land use patterns could encourage fewer miles traveled, lowering emissions of greenhouse gases, criteria pollutants and PM. More compact communities with improved transit service could increase mobility, allowing residents to easily access work, shopping, childcare, health care and recreational opportunities.

Furthermore, if open spaces and desirable locations become more accessible and communities are designed to encourage walkability between neighborhoods and shopping, entertainment, schools and other destinations, residents are likely to increase their levels of physical activity. Research shows that regular physical activity can reduce health risks, including coronary heart disease, diabetes, hypertension, anxiety and depression, and obesity. Measures in the Proposed Scoping Plan encourage Californians to use alternatives to personal vehicle travel that could result in increased personal exercise. To complement these changes, future community developments may evolve to include trails and pedestrian access to major centers. However, where compact development may increase proximity to large sources of pollution, such as high traffic arterials, distribution centers, and industrial facilities, it will be critical to analyze the anticipated and unanticipated impacts and benefits, to ensure that increases in exposure to vehicular air pollution and other toxics and particulates do not occur .

G. California Environmental Quality Act Functional Equivalent Document

The California Environmental Quality Act (CEQA) and ARB policy require an analysis to determine the potential adverse environmental impacts of proposed projects. ARB's analysis of the potential adverse environmental impacts of the Proposed Scoping Plan is presented in Appendix J. The analysis summarizes and discusses the specific strategies in the Scoping Plan that, if adopted and implemented, will reduce greenhouse gas emissions throughout the state. The evaluation is programmatic by necessity; it allows consideration of broad policy alternatives and program-wide mitigation measures at a time when an agency has greater flexibility to deal with basic problems of cumulative impacts. A programmatic document also plays an important role in establishing a structure within which future reviews of related actions can be effectively conducted. The Secretary of California's Resources Agency determined that ARB meets the criteria for a Certified Regulatory Program and requires ARB to prepare a substitute document. This functionally equivalent document (FED) is intended to disclose potential adverse impacts and identify mitigation measures specific to the actions identified in the Proposed Scoping Plan. The analysis generally found that the proposed Low Carbon Fuel Standard, Renewables Portfolio Standard and Water measures have the most potential to cause adverse environmental impacts due to the potential for land conversion when projects are undertaken. Additional environmental analysis will be needed when regulations are adopted and at the individual project level to identify mitigation for project specific impacts.

H. Administrative Burden

ARB conducted a assessment of the administrative burden of implementing the Proposed Scoping Plan recommendation. (HSC §38562 (b)(7)) The recommendation calls for ARB to develop a cap-and-trade program – a market-based regulatory program to cap and reduce emissions from the Industrial, Electricity, Natural Gas, and Transportation sectors. This program would require stringent monitoring and reporting on the part of the regulated community, and comprehensive enforcement on the part of ARB. Sources under the cap would need to analyze the best approach for their company to comply with a cap – assessing the cost of reducing emissions and comparing that to the cost of purchasing emission reductions in a market. Although ARB has not previously developed this type of market regulation, there is extensive experience to draw upon from within California, nationally, and internationally. In addition, the other regulatory components of the recommendation would require ARB and other State agencies to adopt a series of measures requiring regulatory development, outreach to stakeholders and the public, implementation by industry, and enforcement for numerous measures and programs.

I. De Minimis Emission Threshold

A minimum level at which regulations are determined not to apply is termed the 'de minimis threshold.' In recommending a de minimis level, ARB must take into account the relative contribution of each source or source category to statewide greenhouse gas emissions and the adverse effect on small business. (HSC §38561(e)) This threshold acts as a buffer below which the burden of regulation is determined to outweigh the potential harmful effect of the minimal level of emissions. However, it should not be assumed that an individual source of greenhouse gas emissions that is minimal if taken by itself will fall below the threshold. ARB often looks at the aggregate emissions from a source category or related source category when determining regulatory applicability.

A source category may be evaluated as the aggregate of businesses doing the same type of work (e.g., semiconductor manufacturers), a type of equipment (cargo handling equipment, cars), a process or product (cans of pressurized duster), or other aggregated sources of emissions. Emissions of greenhouse gases from any individual entity within these source categories by themselves could be small. However, when emissions from the source category are evaluated, the relative contribution to climate change can be significant.

As ARB developed the Proposed Scoping Plan, potential measures were evaluated against criteria that included the relative contribution of the source to climate change. After this review and considering the level of emissions needed to meet the 1990 target established by AB 32, ARB recommends a de minimis level 0.1 $MMTCO_2E$ annual emissions per source category.[73] Source categories whose total aggregated emissions are below this level are not proposed for emission reduction requirements in the Proposed Scoping Plan but may contribute toward the target via other means.

ARB and other agencies implementing measures included in the Scoping Plan should carefully consider this de minimis level in developing regulations, and only regulate smaller source categories if there is a compelling necessity.

As each regulation to implement the Scoping Plan is developed, ARB and other agencies will consider more specific de minimis levels below which the regulatory requirements would not apply. These levels will consider the cost to comply, especially for small businesses, and other factors.

[73] The Forest sector was not included in determining the de minimis level because this sector serves both as a source and a sink for carbon, making the concept of a de minimis level less applicable.

IV. IMPLEMENTATION: Putting the Plan into Action

Adoption of this Scoping Plan will be a groundbreaking step forward for California. However it is only the beginning of a journey that will last for decades, gradually moving the State into a low-carbon, clean energy future. Putting the Scoping Plan into action will be challenging but with adequate commitment and leadership from Californians up and down the state, it will be a success.

A. Personal Action

The greenhouse gas emission reductions required under AB 32 cannot be realized without the active participation of the people of California. While many of the measures in this Plan must be taken by large sources of emissions, such as power plants and industrial facilities, it is the voluntary commitment and involvement of millions of individuals and households throughout the State that will truly make this California's Plan.

Shifts in individual choices and attitudes drive changes in the economy and in institutions. This dynamic of changing individual behavior will influence California's effort to reduce greenhouse gas emissions. For example, as market forces and environmental awareness encourage more people to drive low-greenhouse gas emitting vehicles, the auto manufacturers will respond with more innovative models and more intensive research. Regulations requiring auto manufacturers to provide these cars will complement the market demand.

This means that thinking about climate change and our carbon footprint will naturally become part of how individuals make decisions about travel, work, and recreation. Some families may choose to purchase a more efficient vehicle when it comes time to replace their current model. Households may choose to lower their thermostat to 68 degrees Fahrenheit during the colder months, and raise it to 78 degrees when air conditioning is required. Some households may choose to swap out incandescent light bulbs for more efficient compact fluorescent lights. Others may choose to install solar water heaters, or arrays of solar electric panels on their roofs to take advantage of renewable energy, and lower their household energy bills. Many households may choose to plant trees to shade and cool their homes, and use landscaping and plants that require less water.

This Proposed Plan recommends measures that will help support many of these individual decisions to improve energy efficiency. Statewide measures and regional efforts will result in programs to promote public transportation or riding in carpools, subsidize the purchase of energy efficient appliances, or provide incentives to better insulate and weatherize older homes. ARB is fully committed to assuring California consumers have the widest possible choice of vehicles that emit fewer greenhouse gases than today's models, including the most advanced technology vehicles produced anywhere in the world.

Californians have embraced statewide programs that support positive change in home and business behavior. In less than two decades, separating household waste and recycling at home and work have become commonplace, as has the widespread purchase of appliances with the Energy Star label to save energy. Reducing our carbon footprint by moving toward a cleaner more efficient economy will produce a wide range of benefits to individuals, through lower energy bills and a healthier environment for all.

Conservation can also play a key role. By employing practices to use our resources more sparingly, consumers can both save money and reduce greenhouse gas emissions. On August 18, 2008, Governor Arnold Schwarzenegger launched the EcoDriving program – a comprehensive effort to save consumers money at the gas pump, reduce fuel use and cut CO_2 emissions. By following a set of easy-to-use best practices for driving and vehicle maintenance, a typical EcoDriver can improve mileage by approximately 15 percent. Furthermore, safety is improved when driving speeds are reduced, a key EcoDriving strategy.

Similarly, consumers and businesses can save money and reduce greenhouse gas emissions by conserving resources at homes, offices and commercial buildings. For example, wireless monitor devices to provide instantaneous energy-usage information inside the home are being developed to show users how many kilowatt hours they're consuming at any given moment – as well as how much it's costing them.[74] Providing real-time information on appliance energy use can greatly assist consumers in conserving electricity use.

Many Californians concerned about climate change have also begun to buy carbon offsets to mitigate the impact of their daily activities. These can take various forms, including options that allow consumers to add 'carbon credits' when buying airline tickets, or paying a small monthly charge on utility bills to buy green power. ARB will be working to establish clear rules for voluntary reductions and offsets that might be used for compliance with AB 32. These rules will also help establish clear guidelines for these types of voluntary carbon credit programs and provide California's businesses and consumers greater assurance that money spent on these programs result in real reductions in greenhouse gas emissions.

For more information about how to reduce one's personal carbon footprint, visit www.coolcalifornia.org. This web site provides a carbon footprint calculator and a "top ten" list of ways to save energy at home.

B. Public Outreach and Education

To be successful, a climate action program needs an effective public outreach and education program. The Proposed Plan calls for a robust statewide program designed to generate awareness and involvement in California's climate change efforts.

[74] The Sacramento Municipal Utility District (SMUD) is subsidizing PowerCost Monitors to 5,000 customers as a part of a demonstration program. [www.smud.org/residential/saving-energy/monitor.html]

The Climate Action Team will convene a steering team that includes State agencies and other public agencies such as the state's air districts, and public and private utilities, which have a strong track record of successful efforts at public education to reduce driving (Spare the Air) or promote energy efficiency and reduce energy demand. With the release of the California Energy Efficiency Strategic Plan, the CPUC has committed to the launch of a new brand for California Energy Efficiency in 2009, focused on energy efficiency opportunities and coordinated with climate change messaging under AB 32. The steering committee will develop a coordinated array of messages and draw upon a wide range of messengers to deliver them. These will include regional and local governments whose individual outreach campaigns can reinforce the broader State outreach themes while also delivering more targeted messages directly tied to specific local and regional programs.

To ensure that all Californians are included in efforts to address climate change, California will also support highly localized efforts at public education and outreach at the community and neighborhood level. This includes service club organizations and existing faith-based communities – churches, mosques and synagogues. Other private-sector entities including businesses and local chambers of commerce will be invited to partner in spreading the word.

1. Involving the Public and Stakeholders in Measure Development

In keeping with the requirements of AB 32 and the legacy of four decades of regulatory development at ARB, we have worked to make this process fully transparent and will continue to do so as regulations to implement the plan are developed. We will continue our efforts to involve the public to the greatest extent feasible at every stage of the process, including informal and formal rulemaking activities. This will include disadvantaged communities and those with localized concerns, as well as affected industries and small businesses.

Local and community meetings and outreach have been and will continue to be a central element of all rulemaking, with State agencies working closely with disadvantaged communities, EJAC, public health experts, and other stakeholders to fully evaluate the impacts associated with California's greenhouse gas emissions reduction strategies. State agencies involved in measure development will continue to meet periodically with communities to assess any challenges to implementation, or to discover possible new measures or approaches. Stakeholders will be invited to participate in the many additional workshops, workgroups and seminars that will be held as individual measures are developed.

2. Education and Workforce Development

The transition to a clean energy future presents California with a tremendous opportunity to continue growing its green economy and to expand the growth of green job opportunities throughout the state. Making this transition will require a technically educated workforce that is equipped with the skills to develop and deploy 21st century technologies. Investments in training, career technical education, worker transition assistance, and collaboration between public and private partners will be key to ensuring that California fully reaps the economic and job opportunities that will accompany implementation of AB 32.

Setting California on track to a low-carbon future beyond 2020 will be a multi-generational challenge. To meet this challenge, climate-related education in schools must be a central element of California's plan. By 2010, California will develop climate change education components to the State's new K-12 model school curriculum as part of the Education and the Environment Initiative (AB 1548, Pavley, Chapter 665, Statutes of 2003). Expanding the knowledge and opportunities of young people to participate in promoting their own and their communities' environmental health will be an important theme for all these efforts. In the meantime, ARB's educational outreach will continue through the Cool California web pages (www.coolcalifornia.org) and the continued support of student educators through the California Climate Champions programs. ARB will also rely on partners throughout the state to develop and display options for curricula that will enhance the K-12, community college, trade technical training programs, and programs at four-year colleges.

The demand for workers to fill green jobs is rising. There are currently more than 3,000 green businesses in the state, accounting for about 44,000 jobs: 36 percent of these jobs are in professional, scientific, and technical services; 19 percent are in construction; and 15 percent are in manufacturing.[75] Some of these jobs are in new fields, yet many others are simply augmentations of existing skills and vocations such as electrical, construction, machining, auto tech, and heating ventilation and air conditioning. As we move toward 2020, tens of thousands of new green job opportunities will be created.[76] Whether these opportunities come in entirely new fields of employment or in existing areas, it will be critical for California to have a trained workforce available.

Ensuring that California can continue to meet the demand for green jobs will require close coordination between workforce development agencies, businesses, State and local governments, labor unions, and community colleges and universities. Many organizations are already developing strategies and identifying steps to simultaneously meet industry workforce needs and help build a more sustainable economy. For instance, the California Labor and Workforce Development Agency (LWDA) provides a comprehensive range of employment and training services in partnership with State and local agencies and organizations. Similar additional efforts will be crucial in ensuring that the transition to a green economy benefits working families in California by providing a steady supply of livable-wage jobs. In the area

of energy efficiency, the California Long Term Energy Efficiency Strategic Plan, adopted by the CPUC, details a vision and supporting strategies for the development of a workforce trained and engaged to achieve California's energy-efficiency objectives.

The following strategies will be key to ensure that California's workforce is equipped to help lead the transition to a clean energy future:

- **Strengthen and expand access to Career and Technical Education (CTE) in California public schools for the next generation of workers who will build a green economy.** Over the past several decades, there has been a steady decline in career and technical education. In 2007, less than one-third of all high school students in the state were enrolled in some form of CTE.[77] To take full advantage of the emerging green economy and meet the goals of AB 32, California needs to expand opportunities for CTE in schools. This could include pursuing strategies such as requiring CTE coursework for all middle- and high-school students; increasing the number of CTE credentialed teachers; expanding investment in facilities and equipment for career and technical education; and aligning educational curricula more closely with the skill and workforce needs of the emerging green economy.

- **Ensure an adequate pipeline of skilled workers who are trained in the new technologies of a greener economy.** While some green jobs will be in new businesses and new occupations, most green jobs are variations of traditional occupations in sectors like construction, utilities, manufacturing and transportation.[78] In light of the fact that forty percent of the nation's skilled workers are slated to retire in the next 5 to 10 years,[79] there is an urgent need for educational and training programs to fill these jobs. Strategies to create a steady pipeline of skilled workers include expanding curriculum choices in schools, colleges, and universities to fully reflect career opportunities available in an economy increasingly centered on clean technologies. Other strategies include offering a greater array of industry- and technology-specific courses that would link directly with postsecondary training such as apprenticeship programs, vocational training, or college.

- **Ensure that California's higher education institutions continue to produce the next generation of clean tech engineers, scientists and business leaders.** In addition to providing valuable research on potential climate-change mitigation and adaptation strategies, California's world-class research institutions are the incubators for many of the clean tech companies that will contribute to

California's environmental and economic future. It will be critical for California to continue to cultivate university research and training programs in a way that takes full advantage of this valuable state resource.

A successful transition to a clean energy future depends heavily on California's ability to provide a well-trained workforce to meet the demands of the growing green economy. ARB and our key partners will continue working throughout the state to ensure that an adequate supply of skilled workers is positioned to take advantage of the growing opportunities for high quality jobs and careers that implementation of AB 32 will bring.

3. Small Businesses

Small businesses play a crucial role in California's economy. As noted in Chapter III, our analysis indicates that this plan will have a net positive impact on small businesses. These impacts are attributable primarily to the measures in the plan that will deliver significantly greater energy and fuel efficiencies. However, as also noted in the analysis, ensuring that these benefits are realized to the fullest potential will require additional outreach and communication efforts by ARB and many other state and local entities.

One of ARB's Early Action measures is designed to help businesses during AB 32 implementation. With our State partners, we are developing an on-line small business "toolkit" designed for small and medium-sized businesses that will provide a one-stop shop for technical and financial resources. Toolkit components will include a business-specific calculator to assess a company's carbon footprint; a voluntary greenhouse gas inventory protocol for measuring greenhouse gas emissions; recommended best practices for energy, transportation, building, purchasing, and recycling; case studies demonstrating how small and medium California businesses have reduced greenhouse gas emissions; program financing resources; peer-networking opportunities; and an awards program to recognize reductions of greenhouse gas emissions among California businesses.

ARB will also continue working with the many business associations, organizations, and other State partners, such as the Small Business Advocate's AB 32 Small Business Task Force, the Labor and Workforce Development Agency, and Business, Transportation, and Housing Agency that have the resources, input and expertise to provide. These partners will help to further develop and implement an effective outreach plan to provide technical assistance to businesses through a variety of means, including attendance at business events, workshops, and working with local economic development agencies.

C. Implementation of the Plan

This Proposed Scoping Plan outlines the regulations and other mechanisms needed to reduce greenhouse gas emissions in California. ARB and other State agencies will work closely with stakeholders and the public to develop regulatory measures and other programs to implement the Plan. ARB and other State agencies will develop any regulations in accordance with established rulemaking guidelines. Table 32 shows the status of the proposed measures in the plan.

Table 32: Status of Proposed Scoping Plan Measures

Existing Laws, Regulations, Policies And Programs
Light-Duty Vehicle Greenhouse Gas Standards (Pavley I)
Renewables Portfolio Standard (to 20%)
Solar Hot Water Heaters
Million Solar Roofs
High Speed Rail
Measures Strengthening & Expanding Existing Policies & Programs
Electricity Efficiency
Natural Gas Efficiency
Renewables Portfolio Standard (from 20% to 33%)
Sustainable Forests
Light-Duty Vehicle Greenhouse Gas Standards (Pavley II)
Discrete Early Actions
Low Carbon Fuel Standard
High GWP in Consumer Products (Adopted)
Smartways
Landfill Methane Capture
High GWP in Semiconductor Manufacturing
Ship Electrification (Adopted)
SF6 in non-electrical applications
Mobile Air Conditioner Repair Cans
Tire Pressure Program
New Measures
California Cap-and-Trade Program Linked to WCI Partner Jurisdictions
Increase Combined Heat and Power
Regional Transportation-Related GHG Targets
Goods Movement Systemwide Efficiency
Vehicle Efficiency Measures
Medium/Heavy Duty Vehicle Hybridization
High GWP Reductions from Mobile Sources
High GWP Reductions from Stationary Sources
Mitigation Fee on High GWP Gases
Oil and Gas Extraction
Oil and Gas Transmission
Refinery Flares
Removal of Methane Exemption from Existing Refinery Regulations

Rulemakings will take place over the next two years. As with all rulemaking processes, there will be ample opportunity for both informal interaction with technical staff in meetings and workshops, and formal interaction. ARB will consider all information and stakeholder input during the rulemaking process. Based on this information, ARB may modify proposed measures to reflect the status of technological development, the cost of the measure, the cost-effectiveness of the measures and other factors before presenting them to the Board for consideration and adoption.

In addition to these existing approaches, AB 32 imposes other requirements for the rulemaking process. Section 38562(b) explicitly added requirements for any regulations adopted for greenhouse gas emissions reductions. ARB also recognizes the need to expand the scope of analysis required when adopting future greenhouse gas emission reduction regulations. These expanded evaluations include the unique enforcement nature of climate change-related regulations and the possible extended permitting considerations and timelines that must be taken into account when establishing compliance dates. An important consideration in developing regulations will be the potential impact on California businesses. The potential for leakage, the movement of greenhouse gas emissions (and economic activity) out of state, will be carefully evaluated during the regulatory development.

As noted above, as the Scoping Plan is implemented and specific measures are developed, ARB and other implementing agencies will also conduct further CEQA analyses, including cumulative and multi-media impacts. ARB must design equitable regulations that encourage early action, do not disproportionately impact low-income and minority communities, ensure that AB 32 programs complement and do not interfere with the attainment and maintenance of ambient air quality standards, consider overall societal benefits (such as diversification of energy resources), minimize the administrative burden, and minimize the potential for leakage. AB 32 requires that, to the extent feasible and in furtherance of achieving the statewide greenhouse gas emission limit, ARB must consider the potential for direct, indirect and cumulative emission impacts from market-based compliance mechanisms, including localized impacts in communities that are already adversely impacted by air pollution, design the program to prevent any increase in emissions, and maximize additional environmental and economic benefits prior to the inclusion of market-based compliance mechanisms in the regulations. As ARB further develops its approach for consideration of these issues in future rulemakings, and updates needed analytical tools and data sets, we will consult with outside experts and the EJAC.

ARB already conducts robust environmental and environmental justice assessments of our regulatory actions. Many of the requirements in AB 32 overlap with ARB's traditional evaluations. In adopting regulations to implement the measures recommended in the Scoping Plan, or including in the regulations the use of market-based compliance mechanisms to comply with the regulations, ARB will ensure that the measures have undergone the aforementioned screenings and meet the requirements established in HSC §38562 (b) (1-9) and §38570 (b) (1-3).

D. Tracking and Measuring Progress

Many State agencies, working with the diverse set of greenhouse gas emissions sources, have collaborated in the process of developing the strategies presented in this plan. As the agency responsible for ensuring that AB 32 requirements are met, ARB must track the regulations adopted and other actions taken by both ARB and other State agencies as the plan is implemented.

The emissions reductions enumerated in this plan are estimates that may be modified based on additional information. As the proposed measures are developed over the coming years, it is possible that some of these strategies will not develop as originally thought or not be technologically feasible or cost-effective at the level given in the plan. It is equally likely that new technologies and strategies will emerge after the initial adoption schedule required in AB 32, that is, regulation adoption by January 1, 2011. If promising new tools or strategies emerge, ARB and other affected State agencies will evaluate how to incorporate the new measures into the AB 32 program. In this way, new strategies ensuring that the commitments in the plan remain whole and that the 2020 goal can be met will be incorporated into the State strategy.

ARB will update the plan at least once every five years (HSC §38561(h)). These updates will allow ARB to evaluate the progress made toward the State's greenhouse gas emission reduction goals and correct the Plan's course where necessary. This section discusses the tracking and measurement of progress that ARB envisions. The Report Cards and audits, along with an evaluation of new technologies – both emerging and those recently incorporated into the Plan – will also provide valuable input into ARB's update process. Continuous atmospheric monitoring of greenhouse gases may also be useful for determining the effectiveness of emission reduction strategies and for future inventory development.

1. Report Card

SB 85 (Budget Committee, Chapter 178, Statutes of 2007) requires every State agency to prepare an annual "Report Card," detailing measures the agency has adopted and taken to reduce greenhouse gas emissions, including the actual emissions reduced as a result of those actions. The information must be submitted to CalEPA, which is then required to compile all the State agency data into a report format, which is made available on the Internet and submitted to the Legislature. The information allows comparisons of each agency's projected and actual greenhouse gas emissions reductions with the targets established by the CAT or the Scoping Plan. This would be the State's 'Report Card' on its efforts to reduce greenhouse gas emissions.

Agencies are also required, as funds are available, to have an outside audit of greenhouse gas-related actions completed every three years to verify actual and projected reductions.

2. Tracking Progress by Implementing Agencies

As the lead agency responsible for implementing AB 32, ARB must track the progress of both our efforts and the efforts of our partners in implementing their respective provisions of this plan. Communication between ARB and the other implementing agencies will be especially important as regulations and programs are developed. In support of the Report Card requirement noted above, ARB will work with CalEPA to develop a process to track and report on progress toward the plan's goals and commitments.

3. Progress Toward the State Government Target

The CAT recently established a State Government Subgroup to work with State agencies to create a statewide approach to meet the Scoping Plan's commitment to reduce greenhouse gas emissions by a minimum of 30 percent by 2020 below the State's estimated business-as-usual emissions – approximately a 15 percent reduction from current levels. State agencies must lead by example by doing their part to reduce emissions and employ practices that can also be transferred to the private sector. The statewide plan will serve as a guide for State agencies to achieve realistic, measurable objectives within specific timelines. This newly created State Government Subgroup will assist State agencies through these steps in a timely manner.

4. Mandatory Reporting Regulation

ARB's mandatory reporting rule, adopted in December 2007, will help the State obtain facility-level data from the largest sources of greenhouse gas emissions in California. This data will help ARB better understand these sources to develop the proposed emissions reduction measures outlined in this plan.

The regulation requires annual reporting from the largest facilities in the state, accounting for 94 percent of greenhouse gas emissions from industrial and commercial stationary sources in California. There are approximately 800 separate sources that fall under the new reporting rules, which include electricity generating facilities, electricity retail providers and power marketers, oil refineries, hydrogen plants, cement plants, cogeneration facilities, and industrial sources that emit over 25,000 tons of carbon dioxide each year from on-site stationary source combustions such as large furnaces. This last category includes a diverse range of facilities such as food processing, glass container manufacturers, oil and gas production, and mineral processing.

Affected facilities will begin tracking their greenhouse gas emissions in 2008, to be reported beginning in 2009 with a phase-in process to allow facilities to develop reporting systems and train personnel in data collection. Emissions for 2008 may be based on best available data. Beginning in 2010, emissions reports will be more rigorous and will be subject to third-party verification. Reported emissions data will allow ARB to improve its facility-based emissions inventory data. Originally, the statewide greenhouse gas inventory was based on aggregated sector data and could not be broken down to the facility level. The facility-level reporting required under the Mandatory Reporting regulation will improve data on greenhouse gas emissions for individual facilities and their emitting processes. This information could also help improve emissions inventories for criteria pollutants, and provide additional data for assessing cumulative emission impacts on a community level.

ARB emissions reporting requirements are expected to be modified over time as AB 32 is implemented.

E. Enforcement

Enforcement is a critical component of all of the State's regulatory programs, both to ensure that emissions are actually reduced and to provide a level playing field for entities complying with the law. To meet the 2020 target this plan calls for aggressive action by a number of State agencies. Each of those agencies will employ its full range of compliance and enforcement options to ensure that planned reductions are achieved. The remainder of this section discusses ARB's portion of the enforcement program in more detail.

ARB has an extensive and effective enforcement program covering a wide variety of regulated sources, from heavy-duty vehicle idling, to consumer products, to fuel standards and off-road equipment. To increase the effectiveness of its enforcement efforts and provide greater assurance of compliance, ARB also partners with local, State and federal agencies to carry out inspections and, when necessary, prosecute violators.

ARB will continue its strong enforcement presence as the State's primary air pollution control agency. A critical function of this responsibility is to ensure that all enforcement actions are timely, effective, and appropriate with the severity of the situation. ARB will also continue its close working relationship with local air districts in the development and enforcement of applicable regulations contained within the Scoping Plan and collaborate with the appropriate State agencies on greenhouse gas emission reductions measures.

For the stationary source regulations called for in the plan, ARB will work closely with the local air districts that have primary responsibility for implementing and enforcing criteria pollutant regulations. Not only are local air districts familiar with the individual facilities and their compliance history, but information contained in district permits can be used to verify the accuracy of greenhouse gas emissions reported by sources subject to ARB mandatory reporting requirements. Using this data, regulators can also examine any correlation between greenhouse gases and toxic or criteria air pollutants as a result of emissions trading or direct regulations.

ARB will also continue to partner with the California Highway Patrol and other State and local enforcement agencies on mobile source and other laws and regulations where joint enforcement authorities apply.

Although many of the measures in the Proposed Scoping Plan are modeled on existing ARB regulations, a multi-sector, regional cap-and-trade program would bring unique enforcement challenges. ARB and CalEPA have begun the process of engaging and consulting with other State agencies, such as California's Department of Justice, Public Utilities Commission, Energy Commission, as well as the Independent System Operator, on market tracking and enforcement. These working group meetings are ongoing and will culminate in a comprehensive enforcement plan to accompany the proposed cap-and-trade program when the Board considers regulatory requirements. This enforcement plan would describe the administrative structures needed for market monitoring, prosecution, and penalty setting. Public input regarding these issues would also be a key part of the public stakeholder process conducted during development of the cap-and-trade programs regulations.

Accurate measurement and reporting of all emissions would be necessary to assure accountability, establish the integrity of allowances, and provide sufficient transparency to sustain confidence in the market. To ensure compliance, ARB would administer penalties for entities that hold an insufficient quantity of allowances to cover their emissions or fail to report their greenhouse gas emissions. Missed compliance deadlines would also result in the application of stringent administrative, civil, or criminal penalties.

This plan recommends that California implement a cap-and-trade program that links with other Western Climate Initiative partner programs to create a regional market system. This system would require California to formalize enforcement agreements with its WCI partner jurisdictions for all phases of cap-and-trade program operations, including verification of emissions, certification of offsets based on common protocols, and detection of and punishment for non-compliance. As needed, California would also work with federal regulatory and enforcement agencies that oversee trading markets, such as the Commodity Futures Trading Commission and the Federal Energy Regulatory Commission. While California would work with other jurisdictions on joint enforcement activities, ARB will exercise all of its authority under HSC §38580 and other provisions of law to enforce its regulations against any violator wherever they may be.

F. State and Local Permitting Considerations

Some of the proposed emissions reduction strategies in this Proposed Scoping Plan may require affected entities to modify or obtain state or local permits. California's existing permit process ensures that health and safety concerns are evaluated, met, and when appropriate, mitigated. The State recognizes the potential for conflicts between various federal, state and local permitting requirements, which may cross various media – air, water, etc. CalEPA is actively involved in identifying and addressing these regulatory overlap issues with the ultimate goal of consolidating permits where feasible while maintaining all permit requirements. Two such examples are CalEPA's digester permit working group and the CalEPA-Air District Compost Emissions Work Group.

ARB recognizes that the permitting process may affect the viability of certain strategies and that the length of the permitting process could affect the timing of emissions reductions.

ARB, along with CalEPA and other State agencies, will continue to evaluate steps to ensure that permit requirements harmonize across the affected media.

This Plan has been developed with an understanding of the important cross-media impacts. These efforts will continue during the implementation of the Plan. Particular focus on the potential permitting impacts and cross-media consequences of a proposed rule will take place during the rulemaking process.

G. Role of Local Air Districts

Local air districts are ARB's partners in addressing air pollution. ARB takes primary responsibility for transportation, off-road equipment and consumer products. Local districts lead in controlling industrial, commercial and other stationary sources of air emissions. AB 32 recognizes the need to develop a program that meshes with local and regional activities. Although AB 32 does not provide an explicit role for air districts, their local presence as advocates for clean air and their resources, experience and expertise in regulating and enforcing rules for stationary sources make them a logical choice to have an important role in several aspects of implementing California's greenhouse gas program. ARB would partner with local air districts to develop and effectively enforce both source-specific requirements on industrial sources, and to enforce related programs, such as the high GWP rules, that affect a large number of local businesses.

ARB and local air districts are also actively working to coordinate emission reporting requirements. Some districts, like the South Coast Air Quality Management District, have developed software to allow their industrial sources to simultaneously report their criteria pollutant emissions to the District and their greenhouse gas emissions to ARB. Many air district staff are being trained as third-party verifiers to confirm the greenhouse gas emissions information provided by industrial sources under the mandatory reporting regulation, and, similarly, could provide verification of voluntary greenhouse gas reductions in the future.

Local air districts will be key in both encouraging greenhouse gas emissions reductions from other regional and local government entities, and providing technical assistance to quantify and verify those reductions. Local agencies are an important component of ARB's outreach strategy.

Many local air districts have already taken a leadership role in addressing greenhouse gas emissions in their communities. These efforts are intended to encourage early voluntary reductions. For example, local districts are "lead agencies" under the California Environmental Quality Act (CEQA) for some projects. In order to ensure high-quality mitigation projects, some districts have established programs to encourage local greenhouse gas reductions that could be used as CEQA mitigation. As the State begins to institutionalize mechanisms to generate and verify greenhouse gas emissions reductions, ARB and the districts must work together to smoothly transition to a cohesive statewide program with consistent technical standards.

H. Program Funding

Administration, implementation, and enforcement of the emissions reduction measures contained in the Proposed Scoping Plan will require a stable and continuing source of funding. AB 32 authorizes ARB to collect fees to fund implementation of the statute. This fall ARB will initiate a rulemaking for a fee program to fund administration of the program.

Approximately $55 million per year will be needed on an ongoing basis to fund implementation by ARB and other State agencies, based on the positions and funding included in the 2008-2009 fiscal year budget. Additional revenues are needed to repay the loans from State funds that were used to pay ARB and CalEPA expenses in the startup of the program. ARB is moving on an expedited schedule to develop a fee regulation and expects to take a regulation to the Board in early 2009, with the aim of beginning to collect fees in the 2009-2010 fiscal year.

V. A VISION FOR THE FUTURE

California has the know-how, ingenuity, research capabilities, and culture of innovation to meet the challenge of addressing climate change. However, reaching the goals we have set for ourselves will not be easy. Successful implementation of many of the proposed programs and measures described in this plan will require strong leadership and a shared understanding of the need to reach viable and lasting solutions quickly.

This challenge will also require establishing a wide range of partnerships, both within California and beyond our borders. We will need to support additional research, and further develop our culture of innovation and technological invention. In order to continue the momentum and the commitment to a clean energy future, we will need to both build on existing solutions and develop new ones.

The following sections lay out some of the elements that will be necessary to forge a broad-based institutional strategy to address climate change both within California and beyond. Also discussed is the need to build partnerships on the regional, national and international levels to ensure that our actions complement and support those being taken on a global scale. This section also looks forward to 2030, showing that California is on the trajectory needed to do our part to stabilize global climate.

A. Collaboration

1. Working Closely with Key Partners

True climate change mitigation will require many parties to work together for a global mitigation plan. California and other states are filling a vacuum created by the current lack of leadership at the federal level. By its bold actions, California is moving the United States closer to a seat at the table among the developed countries that have agreed to reduce their carbon emissions, and lead a new international effort for an agreement to replace the Kyoto Protocol that expires in 2012.

Any national climate program must be built on a partnership with State and local governments to ensure that states can continue their role as incubators of climate change policy and can implement effective programs such as vehicle standards, energy efficiency programs, green building codes, and alternative fuel development.

California will work for climate solutions with key federal agencies, including the U.S. Department of Energy and their national labs, the U.S. Environmental Protection Agency, the U.S. Bureau of Land Management, the U.S. Department of Agriculture, the U.S. Department of Transportation, and others.

Through the Western Climate Initiative and in collaboration with other regional alliances of states, California can promote its own best practices and learn from others while helping to formulate the structure of a regional and ultimately national cap-and-trade program.

2. International

As one of the largest economies in the world, California is committed to working at the international level to reduce global greenhouse gas emissions. As part of this effort, Governor Schwarzenegger and other U.S. governors taking the lead in climate change are co-hosting a Global Climate Summit on Finding Solutions Through Regional and Global Action. This summit, to be held on November 18th and 19th, 2008, will begin a state-province partnership with leaders from the U.S., Australia, Brazil, Canada, China, India, Indonesia, Mexico, the European Union, and other nations, to take urgent steps to contain global climate change and jointly set forth a blueprint for the next global agreement on climate change solutions.

California is also a charter member of the International Carbon Action Partnership (ICAP), an organization composed of countries and regions that have adopted carbon caps and that are actively pursuing the implementation of carbon markets through mandatory cap-and-trade systems. California's continued involvement in ICAP will be very beneficial for sharing experiences and knowledge as we design our own market program.

In addition to participating in ICAP, California hopes to engage developing countries to pursue a low-carbon development path. With developing nations expected to suffer the most from the effects of climate change, California and others have an obligation to share information and resources on cost-effective technologies and approaches for mitigating both emissions and future impacts as changes in climate and the environment occur.

California recognizes the "common but differentiated responsibilities" among developed and developing countries (as articulated in the Kyoto Protocol), but the reality is that rapidly escalating greenhouse gas emissions in developing countries could possibly negate any efforts undertaken in California. To the extent that we are part of the global economy, California's demand for goods manufactured in developing countries further exacerbates growth of greenhouse gas emissions globally. Therefore, it is critical for California to help support the adoption of low-carbon technologies and sustainable development in the developing world.

California can advance the international policy debate through state-provincial partnerships for achieving early climate action in developing countries. This approach envisions commitments by developed countries to provide capacity building through technological assistance and investment support in return for developing countries adopting enhanced mitigation actions. California will consider working with developing countries or provinces that have, at a minimum, pledged to achieve greenhouse gas intensity targets in certain carbon-intensive sectors through mechanisms, such as minimum performance standards or sector benchmarks. California also recognizes that developing countries have the challenge and responsibility to reduce domestic emissions in a way that will promote sustainable development, but not undermine their economic growth.

One possible manifestation of these collaborations could be the establishment of sectoral agreements that help to grow developing countries' economies in a low-carbon manner. In a sectoral approach, energy-intensive sectors adopt programs for reducing greenhouse gas emissions and/or energy use. Such sector-based approaches seem likely to win the support of developing countries and could also reduce concerns in developed countries about international competitiveness and carbon leakage.

A state-provincial partnership related to imported commodities (such as cement) would enable California to provide incentives to reduce greenhouse gas emissions associated with products that are imported by our state. California should continue to develop current relations and existing partnership arrangements with China – now the largest emitter of greenhouse gases in the world – because in addition to other compelling reasons much of the state's imported cement originates in China. California should also work to establish similar relations with India and other countries to share research on both greenhouse gas mitigation and climate change adaptation activities. Projects in the Mexican border region may also be of particular interest, considering the opportunity to realize considerable co-benefits on both sides of the border.

Deforestation accounts for approximately 20 percent of global greenhouse gas emissions. California has set a strong precedent in the effort to incorporate forest management and conservation into climate policy by adopting the CCAR forest methodology in October 2007. California also hopes to engage developing countries, including Brazil and Indonesia, to reduce emissions and sequester carbon through eligible forest carbon activities. Activities aimed at Reducing Emissions from Deforestation and Forest Degradation (REDD) were excluded from the rules governing the first Kyoto commitment period, but there is considerable momentum behind the effort to include provisions that would recognize such activities in a post-2012 international agreement. Providing incentives to developing countries to help cut emissions by preserving standing forests, and to sequester additional carbon through the restoration and reforestation of degraded lands and forests and improved forest management practices, will be crucial in bringing those countries into the global climate protection effort. California recognizes the importance of establishing mechanisms that will facilitate global partnerships and sustainable financing mechanisms to support eligible forest carbon activities in the developing world.

B. Research

1. Unleash the Potential of California's Universities and Private Sector

Bringing greenhouse gas emissions down to a level that will allow the climate to stabilize will take a generation or longer. Many of the ultimate solutions to achieve stabilization will be developed and implemented well into the future. Innovation in energy and climate will come from people who are now in school. These young people will face unprecedented challenges, and they will need both wisdom and imagination to craft solutions. California's respected public and private academic institutions must continue to develop and fund programs based on climate change science that cut across disciplines to address the multi-dimensional aspects of climate change.

2. Public-Private Partnerships

To most effectively address the climate change dilemma, we must encourage collaborations between academia and the private sector. Industry is well-positioned to quickly attack problems. Combining the vast knowledge housed in universities with businesses' acumen and agility can unleash a powerful collaborative force to tackle the problems associated with climate change.

Several important programs have already been initiated at California universities, including Stanford's Global Climate and Energy Project and the University of California at Berkeley's Energy Biosciences Institute (EBI).[80] These and other efforts need to be recognized and encouraged, along with others that can link the results of research directly to policy decisions that the State must make.

Carbon Sequestration

In addition to terrestrial carbon sequestration or natural carbon sinks such as forests and soil, CO_2 can be prevented from entering the atmosphere through carbon capture and storage (CCS). This consists of separating CO_2 from industrial and energy-related sources and transporting the CO_2 to a storage location for long-term isolation from the atmosphere. Potential technical storage methods include geological storage, industrial fixation of CO_2 into inorganic carbonates, and other strategies. Large point sources of CO_2 that may pursue CCS include large power plants, fossil fuel-based hydrogen production plants, and oil refineries.[81]

[80] The EBI is being developed in cooperation with Lawrence Berkeley National Laboratory, the University of Illinois at Urbana-Champaign and BP.

[81] Intergovernmental Panel on Climate Change. *Carbon Dioxide Capture and Storage: A Special Report of Working Group III of the IPCC*. Cambridge University Press, UK; 2005. http://www.ipcc.ch/ipccreports/srccs.htm (accessed October 12, 2008)

According to a 2005 report by the Intergovernmental Panel for Climate Change (IPCC), a power plant with CCS could reduce CO_2 emissions to the atmosphere by approximately 80 to 90 percent compared to a plant without CCS (including the energy used to capture, compress and transport CO_2).[82] While more research and development needs to occur, California should both support near-term advancement of the technology and ensure that an adequate framework is in place to provide credit for CCS projects when appropriate.

The State is currently an active member of the West Coast Regional Carbon Sequestration Partnership (WESTCARB), a public-private collaboration to characterize regional carbon sequestration opportunities in seven western states and one Canadian province. Established in 2003, this research project is comprised of more than 80 public and private organizations. WESTCARB is conducting technology validation field tests, identifying major sources of CO_2 in its territory, assessing the status and cost of technologies for separating CO_2 from process and exhaust gases, and determining the potential for storing captured CO_2 in secure geologic formations.[83]

C. Reducing California's Emissions Further – A Look Forward to 2030

In order to assess whether implementing this plan achieves the State's long-term climate goals, we must look beyond 2020 to see whether the emissions reduction measures set California on the trajectory needed to do our part to stabilize global climate.

Governor Schwarzenegger's Executive Order S-3-05 calls for an 80 percent reduction below 1990 greenhouse gas emission levels by 2050. This results in a 2050 target of about 85 $MMTCO_2E$ (total emissions), as compared to the 1990 level (also the 2020 target) of 427 $MMTCO_2E$. Climate scientists tell us that the 2050 target represents the level of greenhouse gas emissions that advanced economies must reach if the climate is to be stabilized in the latter half of the 21st century. Full implementation of the Proposed Scoping Plan will put California on a path toward these required long-term reductions. Just as importantly, it will put into place many of the measures needed to keep us on that path.

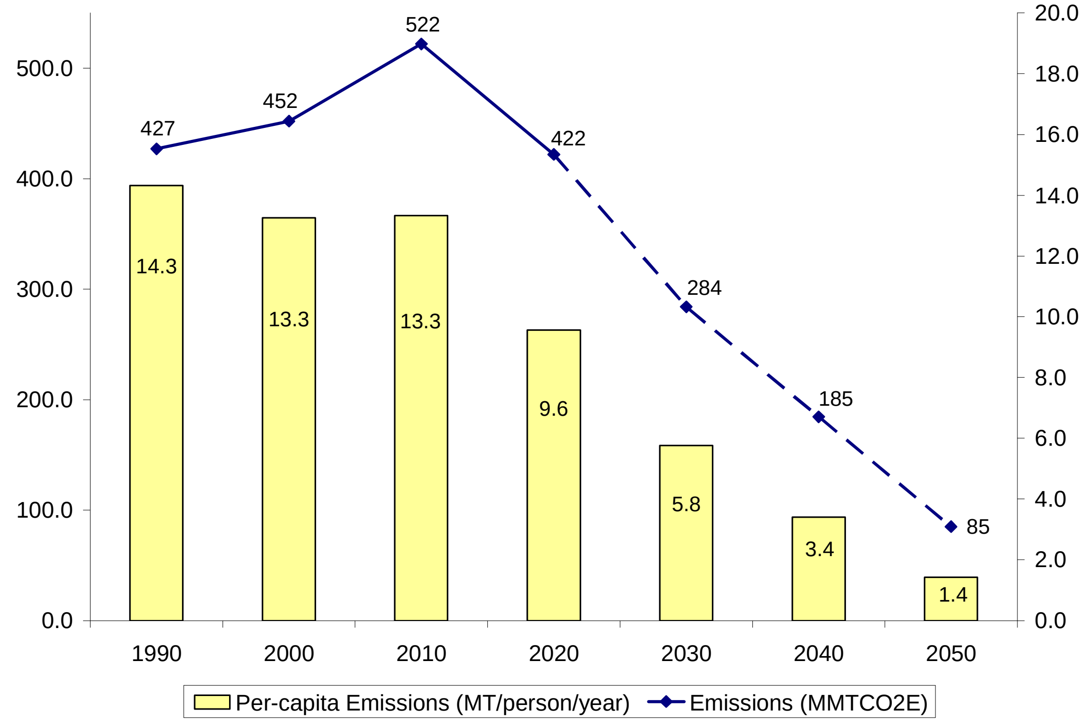
Figure 6 depicts what an emissions trajectory might look like, assuming California follows a linear path from the 2020 AB 32 emissions target to the 2050 goal needed to help stabilize climate. While the measures needed to meet the 2050 goal are too far in the future to define in detail, we can examine the policies needed to keep us on track through at least 2030.

---

[82] Ibid

[83] WESTCARB. *WESTCARB Overview.* http://www.westcarb.org/about_overview.htm (accessed October 12, 2008)

Figure 6: Emissions Trajectory Toward 2050



To stay on course toward the 2050 target our State's greenhouse gas emissions need to be reduced to below 300 $MMTCO_2E$ by 2030. This translates to an average reduction of four percent per year between 2020 and 2030. An additional challenge comes from the fact that California's population is expected to grow by about 12 percent between 2020 and 2030. To counteract this trend, per-capita emissions must decrease at an average rate of slightly less than five percent per year during the 2020 to 2030 period.

Are such reductions possible by 2030? What measures might be able to provide the needed reductions? How do the needed measures relate to the efforts put into place to reach the 2020 goal? All of these are critical questions, and are addressed below.

The answer to the first question is yes, the reductions are possible. Furthermore, the measures needed are logical expansions of the programs recommended in the Proposed Scoping Plan that get us to the 2020 goal. We could keep on track through 2030 by extending those programs in the following ways:

- Using a regional or national cap-and-trade system to further limit emissions from the 85 percent of greenhouse gas emissions in capped sectors (Transportation Fuels and other fuel use, Electricity, Residential/Commercial Natural Gas, and Industry). By 2030 a comprehensive cap-and-trade program could lower emissions in the capped sectors from 365 $MMTCO_2E$ in 2020 to around 250 $MMTCO_2E$ in 2030;

- Achieving a 40 percent fleet-wide passenger vehicle reduction by 2030, approximately double the almost 20 percent expected in 2020;
- Increasing California's use of renewable energy;
- Reducing the carbon intensity of transportation fuels by 25 percent (a further decrease from the 10 percent level set for 2020);
- Increasing energy efficiency and green building efforts so that the savings achieved in the 2020 to 2030 timeframe are approximately double those accomplished in 2020; and
- Continuing to implement sound land use and transportation policies to lower VMT and shift travel modes.

The effects of these strategies are presented in Table 33.

Table 33: Potential Distribution of California Greenhouse Gas Emissions by Sector in 2030

Sector	Potential Emissions ($MMTCO_2E$)
Transportation Fuels*	102
Other Fuel Use*	149
Uncapped Sectors	33
Total	**284**

* Capped sector

With these polices and measures in place, per-capita electricity consumption would decrease by another five percent. Well over half of our electricity demand could be met with zero or near zero greenhouse gas emitting technologies, assuming nuclear and large hydro power holds constant at present-day levels. In response to a lower cap on emissions, existing coal generation contracts would not be renewed, or carbon capture and storage would be utilized to minimize emissions. The remaining electricity generation would come from natural gas combustion either in cogeneration applications or from highly efficient generating units.

By 2030, the transportation sector would undergo a similarly massive transition both in terms of the vehicle fleet and the diversity of fuel supplies. Due to the combination of California's clean car standards (ARB's ZEV program and the Low Carbon Fuel Standard), the number of battery-electric vehicles, plug-in hybrid electric vehicles, and fuel cell vehicles would increase dramatically, to about a third of the vehicle fleet. Flex-fuel vehicles would comprise a large fraction of the remaining fleet, with more efficient gasoline and diesel vehicles making up the difference. Electricity, advanced biofuels, improved gasoline and diesel, renewable natural gas and hydrogen would all play a role in powering this high-tech fleet of efficient vehicles.

Regional land use and transportation strategies would grow in importance and would reverse the trend of per-capita vehicle miles traveled, a reduction of about eight percent below business-as-usual in 2030. With ambitious but reasonable action, statewide passenger vehicle greenhouse gas emissions could be reduced to half of 2020 levels in 2030, which is also about half of business-as-usual for 2030. Efficiency strategies and low carbon fuels for heavy-duty and off-road vehicles, as well as for ships, rail, and aviation, would need to be greatly expanded in order to achieve additional reductions from the transportation sector in 2030.

In tandem with efficiency measures that lower demand for electricity, natural gas and transportation fuels, California's cap-and-trade program would incent large industrial sources as well as commercial and residential natural gas customers to further reduce emissions. By tightening the cap over time, it is expected that facilities in the industrial and natural gas sectors would achieve reductions well beyond those needed to meet the 2020 emissions cap.

The Proposed Scoping Plan proposes several measures for reducing high GWP gases that collectively, will substantially reduce emissions. With a transition toward reduced consumption of these gases, improved containment in their end uses, and substitution of low GWP alternative gases, it is expected that emissions from this sector could decrease by 75 percent between 2020 and 2030.

For uncapped sectors, we assume that the agriculture sector will reduce emissions by about 15 percent between 2020 and 2030. Net forest uptake of CO_2 must be preserved or enhanced, likely through both expansion of forests and reduction in carbon loss from forest fires, which are predicted to increase over this time period. This example assumes a 10 percent reduction in direct landfill emissions from the recycling and waste sector; however, aggressive implementation of the suite of measures proposed in this Plan could further reduce emissions from this sector by 2030.

In total, the measures described above would produce reductions to bring California's statewide greenhouse gas emissions to an estimated 284 $MMTCO_2E$ in 2030. While the potential mix of future climate policies articulated in this section is only an example, it serves to demonstrate that the measures in the Proposed Scoping Plan can not only move California to its 2020 goal, but also provide an expandable framework for much greater long-term greenhouse gas emissions reductions.

D. Conclusion

California's commitment to address global warming has never been greater. The vast amount of interest, support, and input that ARB has received since this plan began to take shape is evidence of a clear understanding of the need to take action and support for the State's efforts to lead the way. The time has come to shift away from a 'business-as-usual' approach to climate change and to move toward the lasting and sustainable goal of a clean energy future.

Reaching our goals will take a great deal of leadership, commitment, and a willingness to embrace new approaches and seek out new solutions. California's plan to reduce greenhouse gas emissions must also take into account the impacts of this transition and be designed in particular to address the needs of low-income communities, small businesses, and California's working families.

Reaching our goals will also require involvement and support from all levels of government in California, and a coordinated effort with other states, regions, and countries. The solutions and technologies we develop here will be used around the world to help others transition to a clean energy future and contribute to the fight against global warming.

Reaching our goals will also require flexibility. As we move forward, we must be prepared to make mid-course corrections. AB 32 wisely requires ARB to update its Scoping Plan every five years, thereby ensuring that California stays on the path toward a low carbon future.

This plan is part of a new chapter for California that in many ways began with the passage and signing of AB 32. It proposes a comprehensive set of actions designed to reduce greenhouse gas emissions in California, improve our environment, reduce our dependence on oil, diversify our energy sources, save energy, create new jobs, and enhance public health. The challenge California has taken on is large but the opportunities are even greater. It is now time to turn this plan into action.

ACKNOWLEDGMENTS

This Proposed Scoping Plan was prepared by the Air Resources Board. This document was made possible by the hard work of numerous contributors. Below is a list of advisory committees and State agencies that directly provided input to this Proposed Scoping Plan.

INTRODUCTION

Climate change is one of the most serious environmental problems facing the world, the United States, and California today. In this State, climate change already is impacting our coastlines, water supplies, agriculture, and public health, and putting millions of acres of forested land at increased risk of fire. These adverse effects will only increase in number and intensity if we do not promptly and substantially reduce pollution of the atmosphere with greenhouse gases (GHGs).

California law provides that climate change is an environmental effect subject to the California Environmental Quality Act (CEQA).[1] Lead agencies therefore are obligated to determine whether a project's climate change-related effects may be significant, requiring preparation of an Environmental Impact Report,[2] and to impose feasible mitigation to substantially lessen any significant effects.[3] Determining significance, however, can be a challenging task. Accordingly, the Governor's Office of Planning and Research in its June 2008 Technical Advisory, "CEQA and Climate Change,"[4] asked the Air Resources Board (ARB) to make recommendations for GHG-related thresholds of significance – identifiable benchmarks or standards that assist lead agencies in the significance determination.[5]

With this Staff Proposal, ARB staff is taking the first step toward developing recommended statewide interim thresholds of significance for GHGs that may be adopted by local agencies for their own use. The task that ARB staff is undertaking is, however, a limited one. Staff will not attempt to address every type of project that may be subject to CEQA, but instead will focus on common project types that, collectively, are responsible for substantial GHG emissions – specifically, industrial, residential, and commercial projects.[6] ARB staff believes that thresholds in these important sectors will advance our climate objectives, streamline project review, and encourage consistency and uniformity in the CEQA analysis of GHG emissions throughout the State.

Staff intends to make its final recommendations on thresholds in early 2009, in order to harmonize with OPR's timeline for issuing draft CEQA guidelines addressing GHG emissions[7] and to provide much needed guidance to lead agencies in the near term.

Public, stakeholder, and local lead agency participation is essential to the success of this project. ARB staff believes that the comment and feedback it receives, along with

additional data and analyses, can form a body of evidence that lead agencies may rely on in adopting thresholds of significance consistent with ARB staff's recommendations.

Because the schedule is expedited, staff's recommendations must necessarily be interim and subject to review and revision as more information becomes available.[8]

BACKGROUND

Significance Under CEQA

A significant effect on the environment means a substantial, or potentially substantial, change in the environment caused directly or indirectly by the project.[9] The incremental effect of a project can be significant when it is cumulatively considerable – that is, when the effect is added to that of other past, present, and reasonably foreseeable probable future projects that also contribute to the problem.[10]

To streamline and facilitate consistency in the significance determination, the CEQA Guidelines[11] encourage agencies "to develop and publish thresholds of significance that the agency uses in the determination of the significance of environmental effects."[12] A threshold of significance is an identifiable quantitative, qualitative or performance level that marks the division between an impact that is significant and one that is not. A threshold of significance gives rise to a presumption, which can be rebutted by evidence that the threshold should not apply to a particular project.

Thresholds of significance must be supported by "substantial evidence." This does not mean that there is one best threshold. In CEQA, substantial evidence "means enough relevant information and reasonable inferences from this information that a fair argument can be made to support a conclusion, even though other conclusions might also be reached."[13]

Climate Change and GHG Thresholds of Significance

"The capacity of the environment is limited, and it is the intent of the Legislature that the government of the state take immediate steps to identify any critical thresholds for the health and safety of the people of the state and take all coordinated actions necessary to prevent such thresholds being reached."[14] But where should a threshold of significance be set for GHG emissions and climate change? This question can be answered only after considering the nature of the environmental problem.

---

[8] ARB staff intends to monitor the implementation of thresholds that are adopted as a result of this process for effectiveness. In the same time frame as the update of the AB 32 Scoping Plan, staff intends to revisit its recommendations and to modify them if necessary.

[14] Public Resources Code, § 21000, subd. (d).

There is a scientific consensus that human activities, chief among them the burning of fossil fuels, profoundly affect the world's climate by increasing the atmospheric concentration of GHG beyond natural levels. Contributing additional GHG pollution to the atmosphere leads to higher global average temperatures, changes to climate, and adverse environmental impacts here in California and around the world.[15] Climate change, caused by "collectively significant projects taking place over a period of time[,]"[16] is a quintessential cumulative impact.

The experts tell us that an additional increase in global average temperatures of just 2 degrees Celsius (3.6 degrees Fahrenheit) is very likely dangerous.[17] With a 2 degree Celsius increase, disastrous effects become likely, including more extreme and more frequent severe weather, more wildfires, greater frequency of droughts and floods, rapid and higher sea level rise, and increased habitat destruction and extinctions.[18] These environmental effects will undoubtedly lead to serious economic, political, and national security disruptions.

In order to reduce the risk of dangerous climate change, we must stabilize atmospheric levels of GHGes at approximately 450 parts per million (ppm) by mid-century.[19] We are fast approaching this limit. Since the beginning of the industrial era, atmospheric concentrations of carbon dioxide, the primary GHG, have climbed to their highest point in the last half-million years, increasing from just under 300 ppm at the turn of the last century, to over 380 ppm today, and rising at about 2 ppm per year.[20]

In response to the challenge of climate change, California has taken a leadership role by committing to reduce its GHG emissions to 1990 levels by 2020 (about a thirty percent reduction in business-as-usual emissions in 2020) and to eighty percent below 1990 levels by 2050.[21] The latter target is consistent with the scientific consensus of the reductions needed to stabilize atmospheric levels of GHGs at 450 ppm by mid-century. Assembly Bill 32, the Global Warming Solutions Act of 2006, codifies the 2020 reduction

[21] Executive Order S-03-05

target and charges ARB with development of a Scoping Plan to map out how the State will achieve this target, including regulatory, voluntary, and market-based mechanisms beginning in 2012.[22]

There is strong need, however, to aggressively address GHG emissions right now. The pollution we contribute to the atmosphere today will continue to have climate impacts for years, decades, and, in some cases, millennia to come. And the longer we delay in addressing the problem, the more we risk being unable to meet our climate objective. CEQA provides a mechanism that is independent of AB 32 through which lead agencies can begin immediately to reduce the climate change-related impacts of the projects that come before them.

<u>What Type of Threshold is Appropriate</u>?

Some have suggested that because of the need for urgent action and the uncertainty of the precise "tipping point" for dangerous climate change, any contribution of GHGs to the atmosphere may be significant – a so-called "zero threshold."

ARB staff believes that for the project types under consideration, non-zero thresholds can be supported by substantial evidence. ARB staff believes that zero thresholds are not mandated in light of the fact that (1) some level of emissions in the near term and at mid-century is still consistent with climate stabilization and (2) current and anticipated regulations and programs apart from CEQA (e.g., AB 32, the Pavley vehicle regulations, the Renewable Portfolio Standard, the California Solar Initiative, and the commitment to net-zero-energy buildings by 2020 (residential) and 2030 (commercial)) will proliferate and increasingly will reduce the GHG contributions of past, present, and future projects.

But any non-zero threshold must be sufficiently stringent to make substantial contributions to reducing the State's GHG emissions peak, to causing that peak to occur sooner, and to putting California on track to meet its interim (2020) and long-term (2050) emissions reduction targets. ARB staff believes that the preliminary interim approaches outlined in this Staff Proposal are consistent with these objectives.

RECOMMENDED THRESHOLDS – CONCEPTUAL APPROACH

ARB staff believes that different GHG thresholds of significance may apply to projects in different sectors. Two primary reasons that sector-specific thresholds are appropriate are: (1) some sectors contribute more substantially to the problem, and therefore should have a greater obligation for emissions reductions, and, (2) looking forward, there are differing levels of emissions reductions expected from different sectors in order to meet California's climate objectives. We also believe that different types of thresholds **–** quantitative, qualitative, and performance-based **–** can apply to different sectors under the premise that the sectors can and must be treated separately given the state of the science and data. A sector-specific approach is consistent with ARB's

[22] Health and Safety Code, § 38500, et. seq.

Proposed Scoping Plan. Consequently, the Staff Proposal takes different, although harmonious, approaches to setting thresholds for different sectors.

The attached flowcharts describe ARB staff's preliminary interim threshold concepts for two important sectors: industrial projects (**Attachment A**) and residential and commercial projects (**Attachment B**). The objective is to develop thresholds for projects in these sectors that will result in a substantial portion of the GHG emissions from new projects being subject to CEQA's mitigation requirement, consistent with a lead agency's obligation to "avoid or minimize environmental damage where feasible."[23] ARB staff is working on a proposal for an interim approach for thresholds for transportation projects and large dairies. Electricity generation is another sector where clarity is needed in the near term. The California Energy Commission (CEC) recently began a public process for identifying an approach for assessing the significance of GHG emissions from power plant projects. CEC staff anticipates concluding that work in Spring 2009.[24]

ARB staff's proposed recommendations for GHG thresholds address projects for which local agencies are typically the CEQA lead agency. In addition to the CEC, other State agencies also serve as lead agencies under CEQA. ARB is coordinating with these State agencies on their approaches to thresholds of significance.

---

[23] California Code of Regulations, title 14, § 15021.

[24] The CEC adopted an Order Instituting Informational Proceeding on October 8, 2008 to address GHG emissions in power plant licensing cases: http://www.energy.ca.gov/ghg_powerplants/notices/2008-10-06_PROPOSED_GHG_CEQA_OII.PDF.

REQUEST FOR PUBLIC COMMENT

ARB staff believes that the concepts in this Staff Proposal can be further developed into interim thresholds of significance. However, staff recognizes that additional analyses and data are needed to fill in some of the blanks, and to understand how the thresholds will operate in the real world.

Comments on all aspects of the Staff Proposal are encouraged. In particular, ARB seeks the active participation of local lead agencies. Staff has identified a few questions to solicit public comment, but this list is not exhaustive.

- Will the recommended approaches have any unintended consequences, for example, encouraging the piecemealing of projects?

- As set out in the attachments to the Staff Proposal, staff proposes to define certain performance standards (*e.g.*, for energy efficiency) by referencing or compiling lists from existing local, State or national standards. For some sub-sources of GHG emissions (*e.g.*, construction, transportation, waste), ARB staff has not identified reference standards. How should the performance standards for these sub-sources be defined?

- Are any of the industrial, residential, or commercial project types eligible for categorical exemptions likely to contribute more significantly to climate change than staff's preliminary analysis indicates?

- For residential and commercial projects, staff has proposed that the GHG emissions of some projects that meet GHG performance standards might under some circumstances still be considered cumulatively considerable and therefore significant. What types of projects might still have significant climate change-related impacts?

(October 24, 2008)

ATTACHMENT A
Preliminary Draft Proposal for Industrial Projects

1. The project is exempt under existing statutory or categorical exemptions.

No

2. (a) The project meets both of the below minimum performance standards, or includes equivalent mitigation measures:

Construction
- Meets an interim ARB performance standard for construction-related emissions.

Transportation
- Meets an interim ARB performance standard for transportation.

AND

(b) The project, with mitigation, will emit no more than ~7,000 metric tons CO2e/yr from non-transportation-related GHG sources (which addresses ~90% of industrial sector GHG emissions). Includes:
- Combustion-related components/equipment;
- Process losses (fugitive, working, evaporative, etc.);
- Purchased electricity; and
- Water usage and wastewater discharge

No

3. Project will have significant GHG impacts. An EIR must be prepared and all feasible GHG mitigation measures implemented.

Yes

Yes

Yes

Presumption of less than significant impacts related to climate change

Presumption of significant impacts related to climate change

[page intentionally blank]

Preliminary Draft Proposal for Industrial Projects

Introduction

CEQA guidelines provide that thresholds of significance can be qualitative, quantitative, or in the form of performance standards. ARB staff's objective is to develop a threshold of significance that will result in the vast majority (~90% statewide) of the greenhouse gas (GHG) emissions from new industrial projects being subject to CEQA's requirement to impose feasible mitigation. ARB staff believes this can be accomplished with a threshold that allows small projects to be considered insignificant. ARB staff used existing data for the industrial sector to derive a proposed hybrid threshold. The threshold consists of a quantitative threshold of 7,000 metric tons of CO2 equivalent per year (MTCO2e/year) for operational emissions (excluding transportation), and performance standards for construction and transportation emissions.

The goal of this effort is to provide for the mitigation of GHG emissions from industrial projects on a statewide level. Over time, implementation of AB 32 will reduce or mitigate GHG emissions from industrial sources. Once such requirements are in place, they could become the performance standard for industrial projects for CEQA purposes. ARB staff intends to pursue this approach in conjunction with development of the regulatory requirements for industrial sources in the Proposed AB 32 Scoping Plan. Staff is proposing the use of a quantitative significance threshold at least until such time that performance standards, such AB 32 regulatory requirements, are in place to ensure mitigation of significant impacts of GHG emissions from projects in the industrial sector.

The performance standards are largely self explanatory and similar to the approaches proposed for residential and commercial projects. The method for deriving the quantitative aspect of the threshold warrants further explanation.

Technical foundation for proposed quantitative aspect of the threshold

Based on the available data, ARB staff found that for the industrial sector, small projects – defined as the portion of new projects that, when viewed collectively, were responsible for only a relatively small amount of emissions – could be allowed to proceed without requiring additional mitigation under CEQA. The question for ARB staff was what line divides these small projects from the rest of the projects that should undergo mitigation to achieve the larger environmental objective.

ARB decided to construct a representative small project and to estimate that project's expected emissions. First, ARB considered the common sub-sources of GHG emissions in the industrial sector. The four main broad emission categories and their approximate statewide contribution to GHG emissions from industrial facilities other than power plants are:

Category	MMTCO2e/year	Percent (%)
Combustion processes	70	63 %
Process Losses (evaporative, fugitive, working, etc.)	15	13 %
Purchased Electricity	18	17 %
Water Use and Wastewater Treatment	7	7 %

As the table indicates, GHG emissions from industrial sources are dominated by combustion emissions. To ensure that significant industrial emissions would be captured by the proposed threshold, ARB staff evaluated industrial boilers because they are a very common piece of equipment, are essential in many energy-intensive industries, and are a top contributor to industrial combustion emissions.

A recent comprehensive survey of industrial boilers by Oak Ridge National Laboratory[25] found that boilers with an input capacity of 10 MMBtu/hr or greater correspond to 93 percent of total industrial boiler input capacity. Based on this data, ARB staff used a natural gas boiler input capacity benchmark of 10 MMBtu/hr which equates to emissions of 4,660 MTCO2e/yr. This capacity benchmark defines a significant combustion source.

As shown in the above table, combustion processes account for 63 percent of the statewide GHG emissions from industrial facilities. Process losses, purchased electricity, and water use and water treatment account for the remaining 27 percent of emissions. Staff applied these proportions to the benchmark combustion emissions estimate (4,660 MTCO2e/yr). The result is an overall emissions estimate of approximately 7,000 MTCO2e/yr for a representative small project that accounts for the four main categories in the table above.

Based on the available data, staff believes that the 7,000 MTCO2e/year benchmark can be used to effectively mitigate industrial projects with significant GHG emissions.

ATTACHMENT B
Preliminary Draft Proposal for Residential and Commercial Projects

1. The project is exempt under existing statutory or categorical exemptions.

Yes → Presumption of less than significant impacts related to climate change

No →

2. The project complies with a previously approved plan that addresses GHG emissions, satisfies (15064(h)(3)), and has all of the following attributes:

- Meets a community level GHG target consistent with the statewide emissions limit in AB 32 and, where the plan will apply beyond 2020, Executive Order S-3-05;
- Is consistent with a transportation-related GHG reduction target adopted by ARB pursuant to SB 375.
- Includes a GHG inventory and mechanisms to regularly monitor and evaluate emissions;
- Includes specific, enforceable GHG requirements;
- Incorporates mechanisms that allow the plan to be revised in order to meet targets; and
- Has a certified final CEQA document (see 15152(f)).

Yes → Presumption of less than significant impacts related to climate change

No →

3. (a) The project meets all of the below minimum performance standards, or includes equivalent mitigation measures.

Construction

- Meets an interim ARB performance standard for construction-related emissions;

Operations

- Meets an energy use performance standard defined as CEC's Tier II Energy Efficiency goal;
- Meets an interim ARB performance standard for water use;
- Meets an interim ARB performance standard for waste;
- Meets an interim ARB performance standard for transportation;

AND

(b) The project, with performance standards or equivalent mitigation, will emit no more than X metric tons CO2e/yr (criteria to be developed).

Yes → Presumption of less than significant impacts related to climate change

No →

4. Project will have significant GHG impacts. An EIR must be prepared and all feasible GHG mitigation measures implemented.

Yes → Presumption of significant impacts related to climate change

Presumption of less than significant impacts related to climate change

Presumption of significant impacts related to climate change

[page intentionally blank]

Preliminary Draft Proposal for Residential and Commercial Projects

Introduction

CEQA guidelines provide that thresholds of significance can be qualitative, quantitative, or in the form of performance standards. ARB staff's objective is to develop a threshold for residential and commercial projects that will substantially reduce the greenhouse gas (GHG) emissions from new projects and streamline the permitting of carbon-efficient projects. To achieve this, staff's preliminary recommendation is to develop a threshold based on clear and stringent performance standards.

Performance standards will address the five major emission sub-sources for the sector: energy use, transportation, water use, waste, and construction. For the energy use performance standard, staff recommends reliance on the California Energy Commission's (CEC) Tier II Energy Efficiency standards for solar energy incentive programs. These standards are consistent with what is needed to meet the state's goal of zero net energy buildings and are continuously updated to reflect energy efficiency best practices. For the remaining sub-sources (water, waste, etc.), staff intends to compile benchmark performance standards as part of its final threshold recommendation. Projects may alternatively incorporate mitigation equivalent to these performance standards.

Staff recognizes that a substantial body of measures to address GHG emissions exists through programs like LEED, GreenPoint Rated, and the California Green Building Code. As work on performance standards moves forward, staff intends to make use of these projects.

In addition, staff proposes that a presumption of non-significance apply only to projects whose total net emissions, after meeting the performance standards or equivalent, are below a specified level. Staff proposes to develop this emissions level as part of its final threshold recommendation.

Discussion of Flow Chart

Box 1: In general, categorical exemptions will continue to apply.

Based on its preliminary analysis, ARB staff believes that projects described in CEQA's categorical and statutory exemption provisions (Articles 18 and 19 of the California Code of Regulations, title 14) will not interfere with achieving the objective to minimize emissions from new projects in this sector. GHG emissions from residential and commercial projects that are described in the categorical exemption language appear to be relatively small from a GHG perspective. For example, staff's preliminary analysis indicates that emissions from a project qualifying for the statutory infill project exemption (Cal. Code Regs., tit. 14, § 15195) will emit approximately 1,600 metric tons (MT)CO2e/yr. Staff believes such infill projects represent some of the largest projects described in the exemption provisions. ARB staff expects to provide additional analyses to support a lead agency's determination that the GHG impact of these project types is less than significant. Staff invites the public and stakeholders to provide further evidence on the application of categorical exemptions to residential and commercial projects.

Box 2: If GHGs are adequately addressed at the programmatic level, the impact of certain individual projects can be found to be insignificant.

As OPR noted in its June 2008 Technical Advisory:

> CEQA can be a more effective tool for greenhouse gas emissions analysis and mitigation if it is supported and supplemented by sound development policies and practices that will reduce greenhouse gas emissions on a broad planning scale and that can provide the basis for a programmatic approach to project-specific CEQA analysis and mitigation…. For local government lead agencies, adoption of general plan policies and certification of general plan EIRs that analyze broad jurisdiction-wide impacts of greenhouse gas emissions can be part of an effective strategy for addressing cumulative impacts and for streamlining later project-specific CEQA reviews.

ARB staff encourages local agencies to take advantage of a programmatic approach to address climate change, consistent with existing law.

If a project complies with the requirements of a previously adopted GHG emission reduction plan or mitigation program that satisfies California Code of Regulations, title 14, section 15064(h)(3), and includes the attributes specified in that provision and Box 2, the lead agency may determine that the project's GHG impacts are less than significant with no further analysis required. Examples of plans that may satisfy this provision include Climate Action Plans incorporated into General Plans that have inventories, an emissions target, suites of specific and enforceable measures to reach that target, monitoring and reporting, and mechanisms to revise the plan to stay on target. Moreover, a prior EIR that "adequately addressed" climate change may be used for tiering purposes. (See Cal. Code Regs. tit. 14, § 15152.)

Box 3: Projects that meet performance standards, or include equivalent mitigation, can be found to be insignificant.

The threshold incorporates performance standards requiring carbon efficiency for each major sub-source of emissions from projects in these sectors. Provided they are set at a sufficiently stringent level, performance standards will dramatically reduce GHG emissions and promote a transition toward zero and low emission projects. In most cases, ARB staff expects that performance standards will need to reach beyond current State mandates by a substantial amount, given that GHG emission reduction goals have not yet been adequately incorporated into State programs. Staff anticipates that performance standards will become more stringent over time.

ARB staff has identified the California Energy Commission's Tier II Energy Efficiency goals as an appropriate performance standard for energy use. Under State law, the CEC is required to establish eligibility criteria, conditions for incentives, and rating standards to qualify for ratepayer-funded solar energy system incentives in California. As part of this effort, the CEC establishes energy efficiency standards for homes and commercial structures, and requires new buildings to exceed current building standards by meeting Tier Energy Efficiency goals. CEC's Tier II Energy Efficiency goals will continue to be updated to achieve energy efficiency best practices, and are consistent with what is needed to meet the California Public Utilities Commission Strategic Plan goals of zero net energy buildings. Currently, the CEC's proposed guidelines for the solar energy incentive program recommend a Tier II goal for residential and commercial projects of a 30 percent reduction in building combined space heating, cooling, and water heating energy compared to the 2008 Title 24 Standards.[26]

For the remaining sub-sources, staff intends to compile benchmark performance standards as part of its final threshold recommendation. ARB staff believes that existing progressive green building standards provide a starting point for performance standards for transportation, water use, waste, and construction-related emissions. Existing green building rating systems like LEED, GreenPoint Rated, the California Green Building Code, and others, contain examples of measures that are likely to result in substantial GHG emission reductions from residential and commercial projects. The key to this approach will be identifying effective GHG reduction measures within these systems. ARB staff would like input from the public and stakeholders on appropriate performance standards for these sub-sources. Performance standards that already exist and have been proven to be effective – at the local, State, national or international level – are preferable.

Under staff's proposed approach, lead agencies would be allowed to find that a project's mitigation is "equivalent" to identified performance standards, thereby allowing for cost-effective and innovative approaches to reducing GHG emissions.

Staff believes that under some circumstances, projects that meet performance standards or include equivalent mitigation measures will have impacts that may still be cumulatively considerable and therefore significant. For this reason, staff recommends that, in addition to meeting performance standards or including

[26] Guidelines for California's Solar Electric Incentive Program Pursuant to Senate Bill 1 - SECOND EDITION - Draft Guidelines can be found at: http://www.energy.ca.gov/2008publications/CEC-300-2008-007/CEC-300-2008-007-D.PDF

equivalent mitigation measures, a project must also emit no more than "X" MTCO2e/yr. Criteria for determining this emissions level have yet to be defined. ARB requests public and stakeholder input on what types of projects might still have significant climate change-related impacts.

Box 4: Presumption of significant impacts.

If a project cannot meet the requirements in the previous boxes, it should be presumed to have significant impacts related to climate change. The lead agency must then prepare an EIR, or other appropriate document, and implement all feasible GHG mitigation measures.

Greenhouse Gas Inventory Data - Graphs

Graph Gallery

The California greenhouse gas (GHG) Inventory compiles statewide anthropogenic GHG emissions and sinks. It includes estimates for carbon dioxide (CO2), methane (CH4), nitrous oxide (N2O), sulfur hexafluoride (SF6), hydrofluorocarbons (HFCs), and perfluorocarbons (PFCs). The current inventory covers years 1990 to 2004.

Scroll down to see summary plots of the current inventory data.

♦ Greenhouse gas: Nitrous oxide (N2O)

► 2006 N2O from Fuel combustion - Distillate —

(Version 2 - Last updated on 03/13/2009)

● GREENHOUSE GAS EMISSION ESTIMATE —

Amount: 964.97 tonnes of N2O Emitted (299,140 tonnes CO2 Eq.)

Basis: Calculation

Calculation: [Fuel Combustion] * [Fuel N2O emission]

Reference: ARB (2009). Upcoming technical support document on GHG inventory methodologies. Version 2 (1990-2006 inventory). Specific questions may be directed to ARB staff, see: http://www.arb.ca.gov/cc/inventory/contacts.htm

● ACTIVITY LEVEL USED IN CALCULATIONS —

Activity: Fuel combustion = 2,910,041,641 gal of Distillate

Basis: Calculation

Calculation: [EMFAC category fuel combustion] * ([Fuel sales] / [EMFAC total fuel combustion])

Reference: ARB (2009). Upcoming technical support document on GHG inventory methodologies. Version 2 (1990-2006 inventory). Specific questions may be directed to ARB staff, see: http://www.arb.ca.gov/cc/inventory/contacts.htm

● PARAMETERS AND CONSTANTS USED IN CALCULATIONS —

Parameter: EMFAC category fuel combustion = 3,284,416,051 gal

Reference: ARB (2007). The California Air Resources Board's EMission FACtors (EMFAC) model was used to calculate emission rates from all motor vehicles, such as passenger cars to heavy-duty trucks, operating on highways, freeways and local roads in California. Model and documentation available online at: http://www.arb.ca.gov/msei/onroad/latest_version.htm

Parameter: EMFAC NOx emission = 340,390,326,602 g (i.e. 340.39 thousand tonnes)

Reference: ARB (2007). The California Air Resources Board's EMission FACtors (EMFAC) model was used to calculate emission rates from all motor vehicles, such as passenger cars to heavy-duty trucks, operating on highways, freeways and local roads in California. Model and documentation available online at: http://www.arb.ca.gov/msei/onroad/latest_version.htm

Parameter: EMFAC total fuel combustion = 3,379,231,038 gal

Reference: ARB (2007). The California Air Resources Board's EMission FACtors (EMFAC) model was used to calculate emission rates from all motor vehicles, such as passenger cars to heavy-duty trucks, operating on highways, freeways and local roads in California. Model and documentation available online at: http://www.arb.ca.gov/msei/onroad/latest_version.htm

Parameter: Fuel N2O emission = 0.332 g / gal

Reference: Long, J. (2007). Personal communication between Kevin Eslinger of CA Air Resources Board and Jeff Long, Air Resources Board Mobile Sources Assessment Branch, September 2007.

Parameter: Fuel sales = 2,994,049,134 gal

Reference: Dwarka R. (2008). Personal communication between Larry Hunsaker of the Air Resources Board and Ronil Dwarka of the California State Board of Equalization. Spring 2008.

Parameter: Vehicle miles traveled = 20,296,159,821 mile

Reference: ARB (2007). The California Air Resources Board's EMission FACtors (EMFAC) model was used to calculate emission rates from all motor vehicles, such as passenger cars to heavy-duty trucks, operating on highways, freeways and local roads in California. Model and documentation available online at: http://www.arb.ca.gov/msei/onroad/latest_version.htm

Constant: Global warming potential of N2O = 310

Reference: IPCC (1996). Second Assessment Report. Climate Change 1995: WG I - The Science of Climate Change. Intergovernmental Panel on Climate Change; J.T. Houghton, L.G. Meira Filho, B.A. Callander, N. Harris, A. Kattenberg, and K. Maskell (eds.); Cambridge University Press. Cambridge, U.K.

- ***GREENHOUSE GAS EMITTED PER UNIT ACTIVITY —***

  Amount: 0.332 g of N_2O per gal of Distillate
  103 g of CO_2eq. per gal of Distillate

♦ Greenhouse gas: Nitrous oxide (N2O)

► 2006 N2O from Fuel combustion - Gasoline —

(Version 2 - Last updated on 03/13/2009)

● GREENHOUSE GAS EMISSION ESTIMATE —

Amount: 4,237 tonnes of N2O Emitted (1,313,457 tonnes CO2 Eq.)

Basis: Calculation

Calculation: ([Vehicle miles traveled] * (0.0318 * ([EMFAC NOx emission] / [Vehicle miles traveled]) + 0.0167)) * ([Fuel sales] / [EMFAC total fuel combustion]) * [Fraction of fuel mix]

Reference: ARB (2009). Upcoming technical support document on GHG inventory methodologies. Version 2 (1990-2006 inventory). Specific questions may be directed to ARB staff, see: http://www.arb.ca.gov/cc/inventory/contacts.htm

● ACTIVITY LEVEL USED IN CALCULATIONS —

Activity: Fuel combustion = 6,346,722,748 gal of Gasoline

Basis: Calculation

Calculation: [EMFAC category fuel combustion] * ([Fuel sales] / [EMFAC total fuel combustion]) * [Fraction of fuel mix]

Reference: ARB (2009). Upcoming technical support document on GHG inventory methodologies. Version 2 (1990-2006 inventory). Specific questions may be directed to ARB staff, see: http://www.arb.ca.gov/cc/inventory/contacts.htm

● PARAMETERS AND CONSTANTS USED IN CALCULATIONS —

Parameter: EMFAC category fuel combustion = 7,108,718,129 gal

Reference: ARB (2007). The California Air Resources Board's EMission FACtors (EMFAC) model was used to calculate emission rates from all motor vehicles, such as passenger cars to heavy-duty trucks, operating on highways, freeways and local roads in California. Model and documentation available online at: http://www.arb.ca.gov/msei/onroad/latest_version.htm

Parameter: EMFAC NOx emission = 68,854,369,222 g (i.e. 68.85 thousand tonnes)

Reference: ARB (2007). The California Air Resources Board's EMission FACtors (EMFAC) model was used to calculate emission rates from all motor vehicles, such as passenger cars to heavy-duty trucks, operating on highways, freeways and local roads in California. Model and documentation available online at: http://www.arb.ca.gov/msei/onroad/latest_version.htm

Parameter: EMFAC total fuel combustion = 16,389,786,721 gal

Reference: ARB (2007). The California Air Resources Board's EMission FACtors (EMFAC) model was used to calculate emission rates from all motor vehicles, such as passenger cars to heavy-duty trucks, operating on highways, freeways and local roads in California. Model and documentation available online at: http://www.arb.ca.gov/msei/onroad/latest_version.htm

Parameter: Fraction of fuel mix = 0.943

Reference: ARB (2009). Upcoming technical support document on GHG inventory methodologies. Version 2 (1990-2006 inventory). Specific questions may be directed to ARB staff, see: http://www.arb.ca.gov/cc/inventory/contacts.htm

Parameter: Fuel sales = 15,509,940,000 gal

Reference: FHWA (various). US Department of Transportation, Federal Highway Administration - Highway Statistics Series. Motor Fuel. Data accessed online at: http://www.fhwa.dot.gov/policy/ohpi/qffuel.cfm

Parameter: Vehicle miles traveled = 153,058,882,143 mile

Reference: ARB (2007). The California Air Resources Board's EMission FACtors (EMFAC) model was used to calculate emission rates from all motor vehicles, such as passenger cars to heavy-duty trucks, operating on highways, freeways and local roads in California. Model and documentation available online at: http://www.arb.ca.gov/msei/onroad/latest_version.htm

IPCC: 1A3biv - Fuel Combustion Activities - Transport - Road Transportation - Motorcycles

Sector: Transportation : On Road : Light-duty Vehicles : Motorcycles

? Greenhouse gas: Nitrous oxide (N2O)

? 2006 N2O from Fuel combustion - Gasoline —

(Version 2 - Last updated on 03/13/2009)

? Greenhouse gas emission estimate —

Amount: 139.28 tonnes of N2O Emitted (43,178 tonnes CO2 Eq.)

Basis: Calculation

Calculation: ([Vehicle miles traveled] * (0.0318 * ([EMFAC NOx emission] / [Vehicle miles traveled]) + 0.0167)) * ([Fuel sales] / [EMFAC total fuel combustion]) * [Fraction of fuel mix]

Reference: ARB (2009). Upcoming technical support document on GHG inventory methodologies. Version 2 (1990-2006 inventory). Specific questions may be directed to ARB staff, see: http://www.arb.ca.gov/cc/inventory/contacts.htm

? Activity level used in calculations —

Activity: Fuel combustion = 58,573,456 gal of Gasoline

Basis: Calculation

Calculation: [EMFAC category fuel combustion] * ([Fuel sales] / [EMFAC total fuel combustion]) * [Fraction of fuel mix]

Reference: ARB (2009). Upcoming technical support document on GHG inventory methodologies. Version 2 (1990-2006 inventory). Specific questions may be directed to ARB staff, see: http://www.arb.ca.gov/cc/inventory/contacts.htm

? Parameters and Constants used in calculations —

Parameter: EMFAC category fuel combustion = 65,605,857 gal

Reference: ARB (2007). The California Air Resources Board's EMission FACtors (EMFAC) model was used to calculate emission rates from all motor vehicles, such as passenger cars to heavy-duty trucks, operating on highways, freeways and local roads in California. Model and documentation available online at: http://www.arb.ca.gov/msei/onroad/latest_version.htm

Parameter: EMFAC NOx emission = 3,572,260,230 g (i.e. 3.57 thousand tonnes)

Reference: ARB (2007). The California Air Resources Board's EMission FACtors (EMFAC) model was used to calculate emission rates from all motor vehicles, such as passenger cars to heavy-duty trucks, operating on highways, freeways and local roads in California. Model and documentation available online at: http://www.arb.ca.gov/msei/onroad/latest_version.htm

Parameter: EMFAC total fuel combustion = 16,389,786,721 gal

Reference: ARB (2007). The California Air Resources Board's EMission FACtors (EMFAC) model was used to calculate emission rates from all motor vehicles, such as passenger cars to heavy-duty trucks, operating on highways, freeways and local roads in California. Model and documentation available online at: http://www.arb.ca.gov/msei/onroad/latest_version.htm

Parameter: Fraction of fuel mix = 0.943

Reference: ARB (2009). Upcoming technical support document on GHG inventory methodologies. Version 2 (1990-2006 inventory). Specific questions may be directed to ARB staff, see: http://www.arb.ca.gov/cc/inventory/contacts.htm

Parameter: Fuel sales = 15,509,940,000 gal

Reference: FHWA (various). US Department of Transportation, Federal Highway Administration - Highway Statistics Series. Motor Fuel. Data accessed online at: http://www.fhwa.dot.gov/policy/ohpi/qffuel.cfm

Parameter: Vehicle miles traveled = 2,539,357,143 mile

Reference: ARB (2007). The California Air Resources Board's EMission FACtors (EMFAC) model was used to calculate emission rates from all motor vehicles, such as passenger cars to heavy-duty trucks, operating on highways, freeways and local roads in California. Model and documentation available online at: http://www.arb.ca.gov/msei/onroad/latest_version.htm

Constant: Global warming potential of N2O = 310

Reference: IPCC (1996). Second Assessment Report. Climate Change 1995: WG I - The Science of Climate Change. Intergovernmental Panel on Climate Change; J.T. Houghton, L.G. Meira Filho, B.A. Callander, N. Harris, A. Kattenberg, and K. Maskell (eds.); Cambridge University Press. Cambridge, U.K.

? Greenhouse gas emitted per unit activity —

Amount: 2.38 g of N2O per gal of Gasoline
737 g of CO2eq. per gal of Gasoline

DOCUMENTATION OF CALIFORNIA'S GREENHOUSE GAS INVENTORY

Last reviewed on May 21, 2009 at 15:20

Back to Index | Year 2000 | Previous year | Next year | Year 2006

? Category: Waste

IPCC: 4D1 - Wastewater Treatment and Discharge - Domestic Wastewater Treatment and Discharge

Sector: Industrial : Wastewater Treatment : Domestic Wastewater : Centralized Anaerobic

? Greenhouse gas: Methane (CH_4)

? 2006 CH_4 from California population - —

(Version 2 - Last updated on 03/13/2009)

? Greenhouse gas emission estimate —

Amount: 19,479 tonnes of CH_4 Emitted (409,065 tonnes CO_2 Eq.)

Basis: Calculation

Calculation: [California Population] * [Per Capita biological organic demand (BOD5)]* [Average number of days per year] * [Proportion centrally treated] * [Proportion anaerobic] * ([Proportion anaerobic without primary treatment] + ([Proportion anaerobic with primary treatment] * (1 - [Proportion of BOD removed in primary treatment]))) * [Maximum methane production capacity] * [Methane correction factor for anaerobic systems]

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

? Activity level used in calculations —

Activity: California population = 37,332,976 person

Basis: Data

Reference: CDOF (2008). California Department of Finance, California Demographic Research Unit: Population Estimates and Projections. Accessed online at: http://www.dof.ca.gov/HTML/DEMOGRAP/ReportsPapers/ReportsPapers.php

? Parameters and Constants used in calculations —

Parameter: Digester gas production rate = 1 cf / person / day

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Maximum methane production capacity = 0.6 g / g

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Methane correction factor for anaerobic systems = 0.8

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Methane correction factor for septic systems = 0.5

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Methane correction for aerobic not well managed = 0.3

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Methane destruction efficiency = 0.99

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Per capita biological organic demand (BOD5) = 90 g / day

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Per capita wastewater flow = 100 gal / person / day

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Proportion aerobic = 0.953

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Proportion aerobic with primary treatment = 0.819

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Proportion aerobic without primary treatment = 0.182

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Proportion anaerobic = 0.047

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Proportion anaerobic with primary treatment = 0.671

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Proportion anaerobic without primary treatment = 0.329

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Proportion centrally treated = 0.9

Reference: CWTRC, 2003. Status Report: Onsite Wastewater Treatment Systems in California. Jointly presented by: California Wastewater Training & Research Center, California State University Chico and USEPA Region 9 Ground Water Office. August 2003. http://www.csuchico.edu/cwtrc/Pages/InfoandReoprtspage.htm

Parameter: Proportion in septic systems = 0.1

Reference: CWTRC, 2003. Status Report: Onsite Wastewater Treatment Systems in California. Jointly presented by: California Wastewater Training & Research Center, California State University Chico and USEPA Region 9 Ground Water Office. August 2003. http://www.csuchico.edu/cwtrc/Pages/InfoandReoprtspage.htm

Parameter: Proportion of BOD removed in primary treatment = 0.325

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Proportion of CH4 in biogas = 0.65

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Proportion of operations not well managed = 0

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Wastewater flow to plants with anaerobic digesters = 17,926,500,000 gal / day

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. ARB staff scaled USEPA's national data down to California pro-rata to yearly population estimates. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Constant: Average number of days per year = 365.2425 day

Reference: USNO (2004). U.S. Naval Observatory, Astronomical Applications Department, Leap Years. Accessed online at: http://aa.usno.navy.mil/faq/docs/leap_years.php

Constant: Methane density = 662 g / m3

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. USEPA 430-R-08-005. Annex 3.10: Methodology for Estimating CH4 and N2O Emissions from Manure Management. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Constant: Global warming potential of CH4 = 21

Reference: IPCC (1996). Second Assessment Report. Climate Change 1995: WG I - The Science of Climate Change. Intergovernmental Panel on Climate Change; J.T. Houghton, L.G. Meira Filho, B.A. Callander, N. Harris, A. Kattenberg, and K. Maskell (eds.); Cambridge University Press. Cambridge, U.K.

? Greenhouse gas emitted per unit activity —

Amount: 522 g of CH4 per person
10,957 g (i.e. 10.96 kg) of CO2eq. per person

Last reviewed on May 21, 2009 at 15:20

Back to Index | Year 2000 | Previous year | Next year | Year 2006

? Category: Waste

IPCC: 4D1 - Wastewater Treatment and Discharge - Domestic Wastewater Treatment and Discharge

Sector: Industrial : Wastewater Treatment : Domestic Wastewater : Effluent Emissions

? Greenhouse gas: Nitrous oxide (N2O)

? 2006 N2O from California population - —

(Version 2 - Last updated on 03/13/2009)

? Greenhouse gas emission estimate —

Amount: 3,197 tonnes of N2O Emitted (991,007 tonnes CO2 Eq.)

Basis: Calculation

Calculation: (([California Population]*[Protein Consumption Rate]*[Fraction of nitrogen in protein]*[Non-consumption protein factor] * [Industrial and commercial codischarge factor]) - [Sewage sludge N not entering aquatic environment]) * [Effluent water emission factor] * [Molecular weight ratio of N2O to N2]

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

? Activity level used in calculations —

Activity: California population = 37,332,976 person

Basis: Data

Reference: CDOF (2008). California Department of Finance, California Demographic Research Unit: Population Estimates and Projections. Accessed online at: http://www.dof.ca.gov/HTML/DEMOGRAP/ReportsPapers/ReportsPapers.php

? Parameters and Constants used in calculations —

Parameter: CA population served by biological denitrification = 272,148 Person

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. ARB staff scaled USEPA's national data down to California pro-rata to yearly population estimates. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Effluent water emission factor = 5.000E-03 g / g

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Emission factor w/o nitrification denitrification = 3.2 g / person

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Emission factor with nitrification denitrification = 7 g / person

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Fraction of nitrogen in protein = 0.16

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Fraction using wastewater treatment plants = 0.9

Reference: CWTRC, 2003. Status Report: Onsite Wastewater Treatment Systems in California. Jointly presented by: California Wastewater Training & Research Center, California State University Chico and USEPA Region 9 Ground Water Office. August 2003. http://www.csuchico.edu/cwtrc/Pages/InfoandReoprtspage.htm

Parameter: Industrial and commercial codischarge factor = 1.25

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Non-consumption protein factor = 1.4

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Protein consumption rate = 41,885 g / person / year

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Parameter: Sewage sludge N not entering aquatic environment = 30,892,798,089 g (i.e. 30.89 thousand tonnes)

Reference: USEPA (2008). Inventory of U.S. Greenhouse Gas Emissions and Sinks: 1990-2006. United States Environmental Protection Agency. EPA 430-R-08-005. Chapter 8: Waste. April 15, 2008. Washington DC. ARB staff scaled USEPA's national data down to California pro-rata to yearly population estimates. http://www.epa.gov/climatechange/emissions/usgginv_archive.html

Constant: Molecular weight ratio of N2O to N2 = 1.571133815

Reference: IUPAC (2006). ATOMIC WEIGHTS OF THE ELEMENTS 2005 (IUPAC TECHNICAL REPORT). Pure Appl. Chem., Vol. 78, No. 11, pp. 2051–2066, 2006.

SCH# 2010081021

FOR PROPOSED

REGIONAL GREENHOUSE GAS EMISSION REDUCTION TARGETS FOR AUTOMOBILES AND LIGHT TRUCKS PURSUANT TO SENATE BILL 375

Date of Release: **August 9, 2010**
Scheduled for Consideration: **September 23, 2010**

Electronic copies of this document can be found on ARB's website at http://www.arb.ca.gov/cc/sb375/sb375.htm. Alternatively, paper copies may be obtained from the Public Information Office, Air Resources Board, 1001 I Street, Visitors and Environmental Services Center, 1st Floor, Sacramento, California 95814, (916) 322-2990.

If you need this document in an alternate format (i.e. Braille, large print) or another language, please contact Ms. Lezlie Kimura Szeto at (916) 322-1504. TTY/TDD/Speech to Speech users may dial 711 for the California Relay Service.

Comments

This report will be considered at a meeting of the Board, which will commence on September 23, 2010. Interested members of the public may present comments orally or in writing at the meeting.

Comments may also be submitted by postal mail or by electronic submittal before the meeting. To be considered by the Board, written comment submissions on the Functional Equivalent Document that are not physically submitted at the meeting must be received no later than 5:00 P.M., September 22, 2010, and addressed to the following:

Postal mail: Clerk of the Board, Air Resources Board
1001 I Street, Sacramento, California 95814

Electronic submittal: http://www.arb.ca.gov/lispub/comm/bclist.php

Please note that for electronic submittal, the webpage provided above has a link for comments on the CEQA Functional Equivalent Document, as well as a separate link for commenting on the Staff Report and proposed targets.

For commenting on the Functional Equivalent Document:
The link is titled "ceqa2010".

The Board requests, but does not require 20 copies of any written submission. Also, ARB requests that written and e-mail statements be filed at least 10 days prior to the meeting so that ARB staff and Board members have time to fully consider each comment.

Please note that under the California Public Records Act (Government Code section 6250 et seq.), your written and oral comments, attachments, and associated contact information (e.g., your address, phone, email, etc.) become part of the public record and can be released to the public upon request. Additionally, this information may become available via Google, Yahoo, and any other search engines.

[Page left intentionally blank]

I. Introduction and Background

The California Environmental Quality Act (CEQA) and Air Resources Board (ARB) policy require an analysis to determine the potentially adverse environmental impacts of proposed projects. This document presents a proposed determination that the establishment of regional greenhouse gas reduction targets (Regional Targets) for passenger vehicles (automobiles and light-duty trucks) and subsequent actions by Metropolitan Planning Organizations (MPOs) to implement policies that achieve those targets may have adverse impacts on the environment. However, we cannot speculate at this time what those specific impacts may be because the manner of implementation of Regional Targets will be at the discretion of MPOs. Further, the overall effect of setting Regional Targets will be beneficial for the environment.

California Public Resources Code §21080.5 allows public agencies with regulatory programs to prepare a plan or other written document in lieu of an environmental impact report once the Secretary of the Resources Agency has certified the regulatory program. The California Secretary for Resources has determined that ARB meets the criteria for a Certified State Regulatory Program (Title 14, California Code of Regulations (CCR) §15251(d)). This certification allows ARB to adopt rules and plans used in ARB's regulatory program without preparing formal CEQA documents such as Initial Studies, Notices of Preparation, Negative Declarations or Environmental Impact Reports (EIRs). As a certified agency, however, ARB is required to prepare a substitute document subject to other provisions of CEQA, such as avoiding significant adverse effects on the environment where feasible. This document considers environmental impacts associated with the proposed action, including cumulative impacts.

CEQA requires a certified agency to provide a description of the proposed action and include one of the following in its environmental document: 1) alternatives to the activity and mitigation measures to avoid or reduce any significant or potentially significant adverse impacts that the project might have on the environment; or 2) a statement that the agency's review of the project has determined the project would not have any significant or potentially significant adverse impacts on the environment, and therefore no alternatives or mitigation measures are proposed (CEQA Guidelines §15252).

ARB is required to set Regional Targets as a first step to achieve the ultimate goal of Senate Bill 375 (Steinberg, Chapter 728, Statutes of 2008) which is to reduce greenhouse gas emissions by reducing passenger vehicle travel. This action is intended to be part of a larger statewide effort to reduce the greenhouse gas emissions that lead to global climate change and to encourage sustainable development. However, because SB 375 was designed to allow regions to independently determine how they will achieve Regional Targets, ARB staff acknowledges there may be a potential for significant adverse impacts on the environment, depending upon the compliance path chosen by each region.

Based on the numerous policies that MPOs may employ to achieve targets and the possibility of varying intensities of deployment of each policy by the regions, there are an infinite number of compliance paths available to the 18 affected regions. Speculation on the adverse impacts within each region associated with those as yet unknown compliance paths is not reasonable at this time; region-specific analyses will be necessary when each MPO prepares either its Sustainable Communities Strategy (SCS) as part of its Regional Transportation Plan (RTP), or its Alternative Planning Strategy.

II. Proposed Project Description: Setting Regional Greenhouse Gas Emission Reduction Targets

SB 375 aligns regional land use, transportation, housing, and greenhouse gas reduction planning efforts. SB 375 requires ARB to set regional greenhouse gas emission reduction targets for passenger vehicles and light trucks for 2020 and 2035 (GC § 65080(b)(2)(A)). The targets are for the 18 MPOs in California. MPOs must develop an element (an SCS) as part of their RTPs to demonstrate how they will achieve the targets, if it is feasible to do so. If it is not feasible for the MPO to achieve its target through an SCS, then the MPO must prepare an Alternative Planning Strategy (APS) which is independent of the RTP.

Prior to setting targets for a region, ARB is required to exchange technical information with each MPO and the affected air districts. GC § 65080(b)(2)(A)(ii). In establishing the Regional Targets, ARB must take into account greenhouse gas emission reductions to be achieved by improved vehicle emission standards, changes in the carbon-intensity of fuels, and other ARB-approved measures that will reduce greenhouse gas emissions in affected regions. GC § 65080(b)(2)(A)(iii). As these factors may change, ARB may revise the Regional Targets every four years, and at a minimum, must update them every eight years. GC § 65080(b)(2)(A)(iv).

The Regional Targets may be expressed in gross tons, tons per capita, tons per household, or in any other metric deemed appropriate by ARB. As discussed more fully in the Staff Report, ARB staff proposes a percent reduction per capita metric for targets. Additionally, each MPO may recommend a target for its region. GC § 65080(b)(2)(A)(v).

Under this framework and based on the data and analysis prepared by the MPOs, ARB staff is recommending the Board adopt the following percent per-capita reduction targets, which together are the Preferred Alternative. The proposed Regional Targets are discussed in detail in the ARB staff report dated August 9, 2010 and posted on the ARB website at http://www.arb.ca.gov/cc/sb375/sb375.htm.

Proposed Greenhouse Gas Reduction Targets for 2020 and 2035
(Percent Change in Per Capita Emissions Relative to 2005)

MPO Regions	2020 (in %)	2035 (in %)
SCAG	-8	-13
MTC	-7	-15
SANDAG	-7	-13
SACOG	-7	-16
8 San Joaquin Valley MPOs[1]	-5	-10
6 Remaining MPOs[2]		
TMPO (Tahoe)	-7	+6
SCRTPA (Shasta)	0	0
BCAG (Butte)	-1	-1
SLOCOG (San Luis Obispo)	-8	-8
SBCAG (Santa Barbara)	+6	+4
AMBAG (Monterey Bay)	+13	+14

The metric for the proposed targets is a percent reduction per capita as compared to a 2005 base year. As part of the Regional Targets Advisory Committee's (RTAC) discussions and later technical discussions with MPOs, this metric was recommended by the RTAC and confirmed through later discussions with the MPOs as a preferred metric because it takes into account several factors.

The proposed metric directly addresses growth rate differences between MPO regions. Addressing growth rate differences between the MPO regions is important given that growth rates are expected to affect the magnitude of change that any given region can achieve with land use and transportation strategies. The per capita metric ensures that both fast and slow growth regions take reasonable advantage of any established transit systems and infill opportunity sites to reduce the region's overall regional greenhouse gas emissions.

The proposed metric also gives regions some "credit" for early actions taken to reduce greenhouse gas emissions since 2005. The per capita metric gives regions that have taken early actions and, as a result have a low level of greenhouse gas emissions per person, responsibility for a lower total reduction

[1] These are placeholder targets for the 8 San Joaquin Valley MPOs, with recognition of model improvements and scenario development efforts. ARB staff will reassess the Valley's progress in 2012.

[2] ARB staff proposes 2020 and 2035 targets that reflect each region's currently projected per capita change from 2005 in greenhouse gas emissions. ARB's target update in 2014 will result in greater emission reductions as a result of better tools to reflect the region's current and projected future land development and transportation infrastructure strategies, and additional time to advance sustainable communities efforts within the regions.

compared to regions that start with a higher level of greenhouse gas emissions per person.

The remainder of this Section II describes the proposed project in context, including significant steps remaining before local or regional environmental analysis can be performed.

A. Steps in SB 375 Implementation

While Regional Targets are the focus of this analysis, their establishment is only the first step among many to implement the planning process described in SB 375 to reduce emissions from passenger vehicle travel.

California's Climate Change Scoping Plan, adopted in December 2008, is the overarching framework for meeting the greenhouse gas emissions reduction goal of the Global Warming Solutions Act of 2006 (AB 32): Return to 1990 emissions levels by 2020. The comprehensive Scoping Plan proposes actions to reduce emissions from major sources, including establishment of Regional Targets for reductions from land use and transportation. The Scoping Plan refers specifically to SB 375 as the process for reducing greenhouse gas emissions through more sustainable land use and transportation planning.

Creating and implementing the plans envisioned by SB 375 involves three steps or phases. The first phase required ARB to convene a Regional Targets Advisory Committee (RTAC) to recommend factors and methods ARB should use to set Regional Targets. This phase was completed in September of 2009. The second phase is for ARB to set Regional Targets, the environmental impacts of which are described in this document. The third phase will be the development of Sustainable Communities Strategies (SCS) and possibly Alternative Planning Strategies (APS) by each MPO to meet Regional Targets in the next update of their Regional Transportation Plan (RTP).

The third phase will require independent analysis by each MPO to determine if there are any potentially significant impacts to the environment resulting from their unique approach, or compliance path, to meeting their area's Regional Target.

B. Regional Transportation Planning Process

SB 375 requires consideration of alternative land use and transportation patterns through pre-existing state and federal planning processes. SB 375 also strengthens the linkage between the Regional Housing Need Allocation (RHNA) process required by State Housing Element Law and the RTP development and adoption process. The development of an RTP requires adherence to local ordinances, state statutes, regulations, and guidelines, as well as federal law. RTPs must take into account local population, growth projections, and local general plans, among other factors.

RTPs are approved by an MPO's board, together with the certification of a CEQA environmental document for the RTP (typically an Environmental Impact Report or EIR) and a transportation conformity determination that ensures the region is on track to meet federal air quality requirements. The documents are then transmitted to the Federal Highway Administration, Federal Transit Administration, and U.S. Environmental Protection Agency for joint consideration. The RTP serves as one of the key documents used by the federal government to identify and fund transportation projects, programs, and services in a region.

Adoption of RTP planning documents as well as the projects listed in them are considered to be projects for purposes of CEQA. To comply with CEQA, MPOs, acting as lead agencies, typically initiate an Initial Study or an equivalent environmental assessment. Based on that work, an environmental document, often an Environmental Impact Report (EIR), is completed. These reports require MPOs to examine the environmental effects of the RTP (i.e. broad policy alternatives, program wide mitigation, growth inducing impacts, and cumulative impacts). After RTP adoption, additional CEQA documents are prepared as needed to address any impacts of individual projects contained within an RTP.

C. Role of MPOs and ARB

Once the Regional Targets are set by ARB, SB 375 requires MPOs to integrate their region's greenhouse gas emission reduction target for automobiles and light-duty trucks into their next RTP development process. Under federal and state law, each of the 18 California MPOs are required to develop an RTP. SB 375 adds a new state requirement to include an SCS, which will contain an underlying land use plan for the RTP tied to the regional transportation system resulting in greenhouse gas emission reductions. The SCS constitutes a fourth element of the RTP, in addition to the three existing elements (policy, financial, and action) that are required in a region's long range RTP.

Since the SCS is part of the RTP, it must also comply with all applicable state and federal requirements, including financial constraint and the use of latest planning assumptions.

SB 375 requires the MPO to prepare an APS only if it cannot feasibly achieve its Regional Target through an SCS. The APS is a separate document from the RTP and is not required to meet federal and state requirements for RTPs, however, the APS may be adopted concurrently with the RTP.

Finally, SB 375 sets out a very limited role for ARB in determining how and whether the Regional Targets will be achieved. Specifically, after establishing targets, ARB's role is to comment on the methodology to be used by each MPO for measuring GHG emissions and then to accept or reject the MPO's determination that their SCS or APS would achieve the targets, if implemented.

Thus, the policy choices relating to how the MPO will meet the targets are left to the discretion of the MPO.

D. General Statewide Impact of Target Setting

The purpose of setting Regional Targets is to implement one of numerous measures to reduce the severe environmental damage caused by greenhouse gas emissions. The Regional Targets will encourage regional planning agencies to deliberately plan in a manner that reduces greenhouse gas emissions from passenger vehicles and light trucks, which will have the added environmental and health benefits of reducing other associated air pollutants from tailpipe emissions. While it is not feasible to predict the nature or extent of localized impacts of individual measures or strategies regions will employ to meet Regional Targets, the overarching statewide impacts of targets we can reasonably conclude will benefit California. This is because the proposed targets would result in a reduction of greenhouse gas emissions of over three million metric tons of CO2 per year (MMTCO2/year) in 2020, and 15 MMTCO2/year in 2035.

SB 375 represents a shift toward planning principles that improve the quality of communities, increase transportation choices of residents, and reduce the frequency and distances Californians drive. Employing these principles in future transportation plans and a growing number of local general and climate action plans will reduce the State's levels of greenhouse gas and other emissions and benefit the public's health and environment.

III. Project Impacts Analysis – Preferred Alternative Levels

A. Incorporation of the Climate Change Scoping Plan Functional Equivalent Document by Reference in Lieu of Tiering

ARB incorporates by reference Appendix J of the Climate Change Scoping Plan (State Clearinghouse Number 2008102060). The programmatic analysis contained in the 2008 Climate Change Scoping Plan Functional Equivalency Document (FED) provides one basis for this environmental analysis. However, ARB staff prepared this analysis as a stand-alone document, rather than a second-tier document based on the Scoping Plan FED.

The establishment of Regional Targets was identified as Measure T-3 in the Climate Change Scoping Plan. The Scoping Plan identified the potential for the Regional Target measure to have a potentially significant impact on: 1) Land Use and Planning; 2) Transportation and Traffic (Appendix J-56, -63); and 3) Public Health and Safety (Appendix J-72). However, the Scoping Plan environmental analysis of these issues concludes that the Regional Target measure would have potentially beneficial impacts on the environment, rather than adverse impacts.

B. Analytical Approach

CEQA discourages forecasting and speculation about potential environmental impacts (CEQA Guidelines §15144 and §15145), though performing an environmental analysis necessarily involves some degree of forecasting. While foreseeing the unforeseeable is not possible, an agency must use its best efforts to find out and disclose all that it reasonably can. Further, if after thorough investigation, a lead agency finds that a particular impact is too speculative for evaluation, the agency should note its conclusion and terminate discussion of the impact.

In evaluating Regional Targets it was necessary to rely upon target-setting scenarios submitted by the MPOs. These scenarios do not represent draft SCS or APS documents, which will be developed by the MPOs over the coming months and years. However, MPO scenarios constitute the best available results of region-specific modeled analysis of policies that may be employed to meet targets, and therefore serve as critical input to ARB staff's analysis of Regional Targets.

In the regional planning process, MPOs will have the exclusive authority to determine whether, and by what means, they will achieve the targets set for them by ARB. MPOs will prepare future SCSs or APSs to demonstrate greenhouse gas reductions consistent with the Regional Targets. Forecasting or speculating about what those RTPs will look like and whether they may cause adverse impacts in any particular region is not possible at this time, and will need to be analyzed and discussed in detail by the MPOs through an established process that involves preparation of EIRs for the RTPs. However, ARB staff's best efforts have resulted in proposed determinations regarding general categories of impacts that could occur in one or more MPO region, depending on their chosen strategies to meet their Regional Target. These impacts are described in Section III.E.

C. Regional and Local Planning Decision Autonomy

While each MPO will need to determine how to meet their Regional Targets, ARB staff acknowledges that meeting Regional Targets may not be possible within an adopted RTP. For example, many emission reduction measures may be beyond the MPO's capacity to fund or authority to implement and therefore cannot be included in an SCS. Additionally, the California Constitution and planning statute clearly indicate that any proposed land use measures in a SCS or APS are solely within a local government's, and not an MPO's discretion to implement (Cal. Const. Art. 11 § 7, GC § 65080(b)(2)(K)). SB 375 contains specific provisions clarifying that neither an SCS nor an APS regulates the use of land. City and county land use policies and regulations are not required to be consistent with the regional transportation plan or APS. (GC § 65080(b)(2)(J))

For these reasons it is crucial for regional planning documents as well as local government planning documents that may implement the Regional Targets, to undergo independent environmental analyses based on the particular proposed action(s) by the MPO, city, or county. Each of these agencies must comply with a body of laws, regulations, and other guidance prior to making decisions, each of which must undergo independent environmental review.

D. Possible Regional Target Compliance Measures

The following is a sampling of the many policies that regions may consider as part of their SCS or APS to reduce greenhouse gases from passenger vehicle travel. The list is based on ARB review of existing academic and practitioner resources and has been shared with the MPOs. Sources for the above list of policies include reports and publications from federal, state, regional and local government agencies and organizations. (See Appendix D: References in the August 9, 2010 Staff Report.) It is not intended to be exhaustive or binding on the MPOs, but is presented to illustrate the numerous and varied compliance options each MPO may choose to employ when developing a region specific strategy to meet their target.

<u>Land Use Policies</u>

Density

- Increase infill and development in areas with existing infrastructure
- Increase opportunities for redevelopment/reuse (e.g., brownfields)
- Increase residential/commercial density near transit (e.g., transit oriented developments)
- Increase use of compact building design in new and existing developments

Diversity

- Increase mixed use development (e.g., residential and commercial uses in infill, reuse/redevelopment or greenfield projects)
- Increase transit oriented development

Design

- Improve connectivity of streets and pedestrian network (e.g., through streets)
- Improve neighborhood and site design (e.g., traffic calming, beautification)

Distance to Transit

- Increase residential/commercial density near transit (e.g., transit oriented development)
- Make developments transit ready

Housing

- Increase local housing for local workforce (e.g., jobs-housing fit, jobs-housing balance)
- Integrate affordable and market rate housing
- Improve accessibility of housing to transit

Open Space and Agricultural Land Conservation

- Reduce pressure on greenfields by directing growth to existing developed areas
- Adopt mechanisms to protect key natural resources

Location of Development

- Locate major regional activity centers near existing development (e.g., "destinations")
- Locate schools in neighborhoods that house the student population or maximize access by alternate modes
- Implement other location-related policies

Incentives

- Provide financial incentives (e.g., grants, tax credits) for non-transportation investments like housing, parks, and storm water management
- Provide regulatory relief (e.g., expedited permit processing)
- Provide recognition programs

<u>Transportation Policies</u>

Transit Facilities and Service

- Expand transit network
- Improve transit facilities (e.g., safety)
- Reduce passenger travel time (e.g., more frequent headways)
- Adopt competitive fare structure

Pedestrian Infrastructure and Environment

- Improve pedestrian facilities and infrastructure
- Improve pedestrian environment (e.g., beautification, access)
- Implement "safe routes to schools" program

Bike Infrastructure and Environment

- Improve bicycle facilities and infrastructure
- Improve cyclist environment (e.g., safety, access)
- Implement "safe routes to schools" program

Interconnectivity Among Alternative Modes

- Improve linkages between modes of travel
- Use Intelligent Transportation System technologies (e.g., "smart card")

Road Quality and Service

- Rehabilitate and maintain pavement
- Use transportation system management (e.g., congestion management)

Parking Management

- Implement effective pricing
- Alter parking requirements and types of supply (e.g., maximum parking, shared parking)

- Improve circulation efficiency through information (e.g., signage)

Employer-Based Commute Trip Reduction

- Encourage telecommuting and flexible/alternative work schedules
- Implement and coordinate use of employee vehicle sharing programs and alternative modes (e.g., incentives for carpool, bike, transit, vanpool use)
- Improve employer parking management (e.g., employee parking "cash out", unbundling parking cost from property cost)

Other Trip Reduction (Commute and Other)

- Implement vehicle sharing programs (e.g., car sharing, bike sharing, park and ride lots)
- Provide local shuttles

<u>Pricing Policies</u>

Parking Pricing

- Implement metered pricing
- Implement parking "cash-out" program

Road User Pricing

- Implement congestion pricing
- Implement High Occupancy Toll (HOT) lanes
- Implement area or cordon pricing
- Implement distance-based (VMT) pricing

Fuel Tax

Additional measures or policies for transportation system management and demand management include:

<u>System Development</u>

- Eliminate or reduce highway and arterial projects that result in additional "general purpose" lane miles
- Expand regional park and ride facilities
- Implement regional bicycle facilities and infrastructure
- Expand high occupancy toll (HOT lanes) system
- Implement traffic signal coordination
- Queue jumps/Bus priority at intersections
- Provide real time transit information
- Speed limit reductions to 55 MPH
- Ramp metering
- Incident management system
- Freeway travelers information system
- Anti-idling traffic codes for commercial vehicles
- Enhance vehicle inspection and maintenance programs
- Operation improvements to relieve bottlenecks

Demand Management

- Eco driver education
- Student carpool programs
- Staggered school class schedules
- On-site child care facilities
- Pay-as-you-drive insurance

E. Potential Environmental Impacts

CEQA and ARB regulations require ARB's functional equivalent document to describe both potentially beneficial and potentially adverse effects of adopting the proposed targets (the Preferred Alternative). The following is a discussion of potential beneficial impacts, project-level adverse impacts, growth inducing impacts, and cumulative impacts. Mitigation measures which could reduce or minimize the potential significant adverse impacts are also discussed in this section.

Beneficial Impacts

Many experts in the fields of land use, transportation, public health and environment have identified the potential for emission-reducing sustainable communities strategies to result in a number of additional benefits, or co-benefits. The implementation of Regional Targets, and the resulting changes in development patterns, may result in a variety of environmental, economic and social benefits. ARB staff agrees that the following list of potential co-benefits, excerpted from the September 29, 2009 RTAC report, provides a concise summary of potential co-benefits of the proposed project:

> "Communities that are well designed and supported by a range of transportation options will significantly reduce greenhouse gas emissions and contribute towards climate change solutions. In addition, many other advantages can result including increased mobility, economic benefits, reduced air and water pollution, and healthier, more equitable and sustainable communities. The Committee recommends that MPOs identify, quantify to the extent possible, and highlight these co-benefits throughout the SB 375 target setting and implementation processes. Co-benefits include the following:
>
> *Increased Mobility*
>
> - Congestion Relief – Fewer cars on the road results in less congestion, which has a number of benefits and helps to improve quality of life.
> - More Transportation Choices – Greater investment in a balanced transportation system and transit-oriented developments can provide increased use of public transportation, and sustainable, healthy transportation options such as walking and bicycle riding.

- Reduced Commute Time and Increased Productivity – Homes closer to job centers can reduce commute time and distance, especially if other modes of transportation are available. People can save time by not sitting in traffic commuting. Public transit provides the opportunity for relaxing or getting work done. Mixed use communities also mean more opportunities to shop and access daily needs near home, saving additional travel time.

Economic Benefits

- Savings – Taking public transit and driving less can save individuals money for fuel costs. Infrastructure/operating costs for transit can also decrease when such costs are spread among an increased number of riders.
- Taxpayer Savings – Services such as maintaining sewer systems, and police and fire services can be more efficient and cost less if they cover more people in less space.
- Neighborhood Economic Development – Increasing density puts more residents within walking distance of neighborhood businesses, providing opportunities for neighborhood economic development.
- Lower up-front infrastructure costs for roads, parking structures, and lower associated environmental impacts.

Reduced Air and Water Pollution

- Less Air Pollution – Reducing the number and length of car and truck trips means less pollution that directly or indirectly creates summertime smog and particulate pollution. Harmful pollution that can cause cancer and other health problems are greatly reduced.
- Improved Water Supply and Quality – Compact development can reduce water use and put less strain on sewer systems. Water quality can also be improved because run off can be filtered by natural lands instead of paved surfaces.

Conservation of Open Space, Farm Land and Forest Land

- The Committee also recognizes there are greenhouse gas benefits inherent in conserving land-based resources including farm and forest land. They play a vital role in California’s agricultural economy and maintaining biological health and diversity in the state. These resources also are capable of sequestering carbon in plant and tree matter as well as in soil.
- Urban parks can provide a great opportunity to enhance the aesthetic quality and function of urban neighborhoods. Urban parks, stream corridors, and trails strategically located can encourage non-motorized modes of transportation. When located in urban areas that people can walk or bicycle to, small parks can

obviate the need for automobile trips to other parts of the city to satisfy everyday recreational needs.

Healthier, More Equitable and Sustainable Communities

- More Opportunities for Active Lifestyles – Increased walking and bicycle riding can contribute to cardiovascular fitness and weight control, both of which can make people healthier and increase quality of life. Increased physical activity can reduce a number of chronic health risks such as obesity, diabetes, heart disease, cancer and depression.
- Less Dependence on Foreign Oil – Using alternative means of transportation and alternative forms of energy and fuel will reduce our dependence on foreign oil, which can help add to national security and economic stability.
- Improved Safety – Thriving, walkable neighborhoods mean more people on the street, helping to improve safety and discourage unlawful activity.
- Greater Housing Choices – Communities can be designed to include a mix of housing options, which can better meet a growing market demand for a variety of housing types. Recent studies indicate that homebuyers are willing to pay a premium to live in a walkable community.
- Preservation of Farmland, Habitat and Open Space – Dense, mixed-use communities can encourage infill and Brownfield redevelopment, thereby preserving open space, farmland and wildlife habitats.
- More Equitable Communities – Social equity issues can be partially addressed by improving local access and transportation to nutritious foods and health care services that are often out of reach in low income communities and communities of color."

<u>Project-Level Adverse Impacts</u>

While various combinations of the measures listed and referenced above in Section III.D. should have the effect of reducing greenhouse gas emissions and creating some combination of the above-listed co-benefits from the regions' transportation systems, there may be potential adverse consequences from implementing these measures. ARB cannot anticipate what development policies, if any, will be adopted and implemented at the regional or local level.

MPOs will need to take these potential impacts into account when developing RTPs, and local government agencies will need to take these into account when approving subsequent site-specific projects in furtherance of the RTPs.

The nature and extent of any of the following potential impacts is difficult to predict. There are numerous and varied compliance options available to meet

Regional Targets. In addition, ARB is not able to speculate about the nature of the SCSs or APSs that may be developed and implemented by the 18 regions. Therefore, the list of impacts below is speculative, at best. However, if one of the purposes of SB 375 is to encourage more compact, mixed-use, urban infill and redevelopment activity along transportation corridors, then it is reasonable to assume that some of the following impacts may occur, although the extent of the impacts and the specific locations where the impacts will occur cannot be predicted.

Use of individual measures or combinations of measures in an SCS or APS may lead to development activity (projects) that could have the following significant adverse impacts:

Air Quality
Placement of sensitive receptors close to high traffic areas where exposure to criteria air pollutants is increased, could create potential health hazards in localized areas. This could occur if new housing and other sensitive receptors, such as schools, are developed close to transportation corridors such as roads and freeways.

Traffic Congestion
Increased traffic congestion in localized areas or on individual roadways could occur as a result of additional residential and/or commercial development in existing urbanized areas where the road and transit systems are not adequate to handle the increased amount of vehicle traffic.

Population Growth
Substantial population growth in localized areas or communities could occur where new infill development or redevelopment is approved at greater densities or concentrations within existing urban centers, existing neighborhoods, or along major transit routes.

Displacement of Residents
Displacement of existing residents and/or businesses due to redevelopment could occur in situations where existing residential and/or commercial properties will be replaced with new infill development.

Utilities and Services
Requirement for new, expanded or altered utility and service systems to accommodate increased concentration of development (i.e. increased density) could occur in situations where the capacity of existing infrastructure (roads, sewers, water lines, power lines) in existing developed areas must be expanded or rehabilitated as a result of increased levels of residential and non-residential development.

Noise
Increased noise pollution in areas surrounding new development or redevelopment sites could occur as a result of urban infill development that places sensitive receptors (homes, schools, parks) in close proximity to noise from adjacent transportation corridors, commercial centers, or other noise generators.

Light and Glare
Increased light pollution in areas surrounding new development or redevelopment sites could occur as a result of intensified development and infill development that places sensitive receptors (homes, schools) in close proximity to uses that require night-time lighting such as transit stops, sports fields, and commercial signage.

Aesthetic/Visual Effects
Changes could occur in the visual character or aesthetics of areas in or adjacent to new development or redevelopment sites. New development or redevelopment may involve increased building heights and reduced setbacks between buildings, changing the visual character of a neighborhood and potentially obstructing views.

<u>Growth-Inducing Impacts</u>

Growth inducement occurs when an activity removes an obstacle to growth or accelerates normal rates of growth. The proposed project will not have a growth inducing impact because it will not influence the amount or rate of population growth in the State. SB 375 anticipates that the State's population will grow and encourages regions to develop plans for accommodating that growth. The proposed project will have no effect on demographics, population growth rates, or external factors such as immigration policy that might influence the rate of growth in the State. Population projections used for SCS planning will be based on regional forecasts and state projections.

SB 375 is intended to reduce greenhouse gas emissions as a result of better coordinated transportation and land use planning that generally commits fewer petroleum and other resources to accommodate a given level of population growth. There should be no net increase or decrease in overall growth resulting from the proposed project; instead the proposed project calls for an incremental decrease in per capita greenhouse gas emissions, even as the State's population increases.

<u>Cumulative Impacts</u>

The only identifiable cumulative impact of the proposed project that is not speculative is the change in greenhouse gas emissions from business as usual.

As discussed above, this is a positive impact in that greenhouse gas emissions are expected to be reduced from business-as-usual levels.

Using the data provided by the MPOs over the past four months, the proposed targets would result in a reduction of greenhouse gas emissions of over three million metric tons of CO2 per year (MMTCO2/year) in 2020, and 15 MMTCO2/year in 2035. When these reductions are applied to the most recent statewide 2020 emissions forecast, the emissions target for passenger vehicles in California's 2008 Climate Change Scoping Plan is met.

Given the numerous potential compliance measures that may or may not be combined in myriad ways within individual regions, quantification or even a qualitative discussion of the cumulative impacts of potential adverse impacts identified above for any single region are even less certain than the already speculative individual impacts identified and therefore cannot be estimated at this time.

Potential Mitigation Measures

Future actions that may be taken by regional and local agencies to implement the Regional Targets will be subject to local control and these actions will be required to undergo independent CEQA review, at which time the potential for adverse impacts and appropriate mitigation measures will be analyzed and implemented.

The following are general mitigation strategies that could be employed to mitigate the potential adverse impacts identified in section III.E. above. ARB does not have the authority to implement any of the following mitigation measures, as these measures are the responsibility and within the control of regional and local agencies that may act later to implement the Regional Targets through adoption of regional and local plans (see Section II.A.-C. above). In addition, the selection of appropriate mitigation measures must be made by the regional or local agency in the context of the particular action being proposed.

This following is not intended to be a comprehensive list of potential mitigation measures. Each regional and local agency that proposes to implement the Regional Targets in an SCS, APS, or local plan or project must determine on a case by case basis, the necessity and feasibility of mitigation measures that are appropriate to a specific later action being taken.

Air Quality

The potential exposure for residents is place-specific and varies due to regional characteristics and the intensity of vehicle emissions from roadways. Exposure to air pollutants for residents living in close proximity to freeways and arterial roadways can be reduced through consideration of project location, appropriate site design and building design, including: sensitive placement of residential buildings on the development site, use of natural and manmade buffers (e.g., vegetation, soundwalls), and where feasible, constructing transportation corridors below grade; and through use of appropriate indoor air filters, placement of buildings as far away from roadways as possible, designing building air intakes to be downwind and away from roadways, and limiting the number of openable windows on sides of buildings facing busy roadways. Site and building design should be considered in the context of a broader regional strategy for air pollution control measures.

Traffic Congestion
Adopt and implement trip reduction and traffic calming measures in areas with high vehicular traffic. Reduce traffic congestion through implementation of parking management programs, provision of adequate bike and pedestrian facilities, and establishment or expansion of transit opportunities. Conduct project-specific traffic analyses where warranted and require appropriate mitigation measures as a condition of permit approval. Local traffic mitigation should be considered in the context of a broader regional strategy for transportation and traffic management.

Population Growth
Adopt and implement local land use and zoning policies that establish building density or population density standards for neighborhoods, including designation of high density areas suitable for compact urban development. Plan for areas within existing communities where growth can be accommodated with appropriate supporting infrastructure, including public services and transportation access.

Displacement of Residents
Adopt and implement local regulations to provide replacement housing within the community for residents who are displaced as a result of redevelopment projects. Comply with all state and federal laws and regulations providing relocation benefits and services. Require development projects to include affordable housing units within the project that may be occupied by displaced residents.

Utilities and Services
Adopt and implement location-specific utility master plans and infrastructure plans to plan for increased capacity of sewer, water, and storm drainage facilities in existing urban areas that are planned for new growth, consistent with local land use policies. Adopt appropriate financing mechanisms to ensure that new development pays its fair share toward the provision of required public services such as fire and police protection.

Noise Pollution
Adopt and implement local noise standards and noise control measures, including limits on decibel levels and/or performance standards for indoor and outdoor noise levels. Project design should ensure that stationary noise sources are placed as far as possible from sensitive receptors to meet local noise

standards. Adopt and implement building acoustical insulation standards where setbacks and sound barriers do not sufficiently reduce indoor noise levels. Limit hours of operation of construction activities and other noise-generating activities to mitigate impacts on residents and other sensitive receptors. Conduct project-specific noise evaluations where warranted and require appropriate noise mitigation as a condition of permit approval.

Light and Glare
Adopt and implement local design guidelines, lighting standards, site development standards and building standards to minimize light and glare impacts on sensitive receptors. Regulate the type and placement of street lighting, parking lot lighting, building exterior lighting, reflective building materials, lighted outdoor signage, and lighting used in landscaping, to ensure sensitive receptors are protected. Conduct project-specific light and glare evaluations where warranted and impose appropriate mitigation measures as a condition of permit approval.

Aesthetic/Visual
Adopt and implement local design guidelines and other policies and regulations that protect scenic views and avoid visual intrusions through both site design and building design. Design buildings and other structures to minimize contrast in scale, massing, color and grading between the project and surrounding areas. Make use of natural landscaping as a screen or to soften contrast. Relocate or avoid development that may impact state and locally designated scenic highways and vistas. Conduct project-specific aesthetic/visual evaluations where warranted and impose appropriate mitigation measures as a condition of permit approval.

<u>Unavoidable Adverse Impacts</u>

It is too speculative to determine whether these or other mitigation measures will be available or effective in reducing potential site-specific impacts to a less than significant level, without knowing the specific characteristics of the future actions that might be taken by other agencies. While it is likely that future actions by regional and local agencies will be governed by their own regulations, development standards, and environmental performance measures which will serve to mitigate the impacts of any given future action, ARB does not have a basis for concluding that any future adverse impacts will be adequately mitigated.

In the absence of evidence to support a finding that any potential future impact will be mitigated to a less-than-significant level, ARB staff concludes that there may be unavoidable potential impacts of Regional Target setting, as a result of future implementing actions by regional and local agencies. This conclusion is not intended to pre-determine any environmental determinations that must be made in the future by regional or local agencies on a case-by-case basis. These future determinations must be made in the context of the particular action (project) that is being considered for approval.

IV. Project Alternatives

CEQA and ARB regulations require ARB's functional equivalent document to describe and evaluate a range of reasonable alternatives to a proposed project that would feasibly attain most of the basic objectives of the proposed project but would avoid or substantially lessen any of the significant adverse impacts of the proposed project (CEQA Guidelines §15126.6(a), 17 CCR § 60006). The range of alternatives required in an EIR is governed by the "rule of reason" that the EIR set forth only those alternatives necessary to permit a reasoned choice. An EIR need not consider an alternative whose effect cannot be reasonably ascertained and whose implementation is remote and speculative (CEQA Guidelines §15126.6(f)(3)).

ARB analyzed five possible alternatives to the proposed project:

- No project (Alternative 1)
- Increase proposed targets substantially (Alternative 2)
- Decrease proposed targets substantially (Alternative 3)
- Use an absolute emissions metric instead of a per capita reduction metric (Alternative 4)
- Use a vehicle miles traveled metric instead of a per capita reduction metric (Alternative 5)

A. Alternative 1 – No Project

ARB staff acknowledges that MPOs and local governments throughout the State are already independently improving and integrating transportation and land use practices consistent with the intent of SB 375. Setting Regional Targets is designed to foster these pre-existing planning efforts by setting ambitious achievable targets for each region. Without Regional Targets, future land use and transportation decisions will continue to promote change but are likely to take longer in overcoming current business as usual practices because:

- Local governments and developers will not be able to utilize CEQA streamlining incentives available from SB 375;
- It will be more difficult to leverage grants and other funding sources without being able to quantify data and staffing needs necessary to minimize environmental impacts due to growth; and
- Without targets collaboration and communication between MPOs is less likely as they develop and refine lower-impact planning strategies.

Without Regional Targets, it is likely that statewide planning improvement efforts will advance at a slower pace than with Regional Targets. This could result in regional transportation plans that do not minimize greenhouse gas related environmental impacts and, due to population growth and the vehicle miles travelled associated with it, erode gains made by other greenhouse gas reduction measures such as introducing cleaner vehicles and fuels to California. For these reasons, ARB staff has concluded that Alternative One has greater adverse environmental impact than the proposed project and should not be pursued.

Under CEQA, the alternatives are required to feasibly obtain most of the basic objectives of the proposed project. For this reason, it is important to note that SB 375 requires ARB to prepare and approve regional greenhouse passenger vehicle emission reduction targets for the State's 18 MPOs (GC § 65080(b)(2)(A)). If targets were not adopted (i.e., the "No Project" alternative) ARB would fail to fulfill the legal mandates specified in SB 375. While a No Project alternative might reduce at least some of the identified potential adverse impacts, it would be outweighed by foregone greenhouse gas emission reductions and would not meet the statutorily mandated target-setting objectives of the proposed project.

B. Alternative 2 – Increase Proposed Targets Substantially

Over the past year and a half ARB staff has worked closely with MPOs and stakeholders in an effort to set the most ambitious achievable Regional Targets. It has been widely acknowledged that if targets are set too high (more ambitious but less achievable) many MPOs would need to use an APS rather than SCS to demonstrate achievement of their targets. By using an APS rather than an SCS it becomes less likely that:

- Extensive and comprehensive environmental review is conducted on the region's plan to meet targets since the APS appears not to need CEQA review;
- Local governments and developers have multiple opportunities to utilize CEQA streamlining incentives and therefore a cost-effective means to construct sustainable projects; and
- Real long-term sustainable planning reforms are able to assist statewide efforts in achieving AB 32 greenhouse gas emission goals to minimize the effects of global climate change.

There are many valid reasons an MPO may need to temporarily rely on an APS for one planning cycle, for example a short-term decrease in funding. This is, however, different than setting targets that ensure the majority of MPOs must rely on an APS over the long term to meet targets.

For these reasons, if targets are substantially increased from proposed levels the actual gains of that increase are far less likely to ever come to fruition. Many or even most MPOs would likely adopt an APS and the status quo development patterns could continue for the foreseeable future because the incentives designed into SB 375 are no longer attainable. In addition, even if Alternative 2 did not trigger substantially more APSs, increased use of the compliance measures identified above for SCSs would likely produce more of the identified potential adverse impacts. Therefore ARB staff has concluded that Alternative Two has greater adverse environmental impact than the proposed project and should not be pursued.

C. Alternative 3 – Decrease Proposed Targets Substantially

Decreasing the target may have equally adverse effects as increasing them. By reducing Regional Targets, it becomes increasingly more likely that each region can adopt an SCS strategy that closely resembles past RTPs making it possible for many projects within an RTP to continue past patterns of leap frog development and sprawl. Since SB 375 provides CEQA streamlining benefits to projects that are consistent with an SCS that meets the region's target, these less sustainable projects will be more easily approved which is counter to the intent of the statute. This alternative is likely to result in:

- Failure to foster further investment and development in regional models, jobs-housing balance and jobs-housing fit, diversity in available housing, and transportation alternatives;
- Maintenance of cost incentives for developers and landowners to convert agricultural and greenfield lands for development, rather than taking advantage of infill opportunities; and
- Erosion of the gains made with improved vehicle technologies and fuels by continuing the trend of growth in vehicle miles traveled (VMT).

We acknowledge that substantially decreased targets could in theory reduce the number and severity of potential adverse impacts identified above for the proposed project. However, as described here for Alternative 3, substantially decreased targets would not only undermine the fundamental statutory objectives for target-setting but might actually worsen the existing baseline situation by allowing CEQA streamlining for business-as-usual developments, and potentially causing other environmental impacts associated with sprawl development (such as loss of wildlife habitat and agricultural lands). For these reasons ARB staff concludes that Alternative Three has greater adverse environmental impact than the proposed project and should not be pursued.

D. Alternative 4 – Use a Total Emissions Metric Rather Than a Percent Reduction Per Capita Metric for Proposed Targets

SB 375 gives ARB discretion to use any metric it deems appropriate. The rationale for the per capita reduction target is explained in the description of the proposed project. The Regional Targets could be expressed as a reduction in the total amount of greenhouse gas emissions, in million metric tons, that must be achieved by each region, by the years 2020 and 2035. This would involve converting the percent per capita reduction targets to total million metric tons of greenhouse gas emissions that must be reduced.

Using this alternative metric would not have the advantages of the percent per capita reduction metric which is proposed. The per capita metric is a relative metric. The benefit of this is that as the assumptions for 2005 change, making the 2005 emission levels higher or lower, the target increases or decreases appropriately. An absolute metric, as represented by this alternative, does not adjust to changing assumptions, and therefore may require an excess of emission reductions (if 2005 emissions decrease) or too few emission reductions (if 2005 emissions increase). At the same time, the absolute emission reduction metric ensures that overall emissions are decreasing, but not necessarily equitably across regions. Some regions may not experience the population growth that they expect, in which case they would be obligated to reducing an absolute amount of emissions with no growth to accomplish it. Other regions may grow faster than anticipated at the time that the absolute target was set, thereby making it easier to achieve the target as compared to the slower growth regions.

The total emissions target has the disadvantage of not being responsive to changing assumptions, especially in population growth, and it may handicap regions that are slow-growing while being easier to achieve for fast growth regions. Alternative Four does not provide the ability to address growth rate differences among the regions and could result in unfairly distributed emission reduction burdens if assumptions were to change after the targets are set. For these reasons, ARB staff concludes that Alternative Four is less desirable than the proposed project and should not be pursued.

E. Alternative 5 – Use a Vehicle Miles Traveled (VMT) Metric Rather Than An Emission Metric for Proposed Targets

SB 375 gives ARB discretion to use any metric it deems appropriate. The statute requires the target to result in a reduction of greenhouse gas emissions, not VMT. While there is a correlation between emissions and VMT, they are not necessarily interchangeable or directly related. By setting a VMT reduction metric, there is no guarantee that consistent and progressive reductions in greenhouse gas emissions will occur. Using a VMT metric may therefore interfere with meeting the statutory mandate to reduce emissions.

Staff concluded a greenhouse gas emissions metric was preferable to a VMT metric due to its simplicity. Over the past several years the public, through various forms of the media, has become increasingly aware of the potential effects of global climate change. The costs and benefits associated with implementation efforts to reduce the effects of global climate change have been expressed in emissions levels. This metric has also been used in state and federal policy discussions. Therefore, while staff will continue to collect information related to vehicle miles traveled the proposed metric should be expressed as emissions levels.

For these reasons, ARB staff concludes that Alternative Five is less desirable and may have greater environmental impact than the proposed project and should not be pursued.

F. Rationale for Selecting the Preferred Alternative (Proposed Regional Targets)

The purpose of alternatives is to identify ways to avoid or reduce the potential adverse impacts of the proposed project, but still allow most of the project objectives to be met. While it is difficult to say with certainty what the particular adverse impacts of the proposed project would be, for the reasons explained in this document, it is similarly difficult to predict whether any of these alternatives would result in better environmental outcomes than the proposed project. However, based on the analysis above, several of the alternatives have the potential to result in greater adverse effects as compared to the proposed project. Others do not meet the basic project objectives.

- Alternative 1 does not meet project objectives and could result in greater environmental impacts because there would be no state goals for reducing emissions.
- Alternatives 2 and 3 could result in greater environmental impacts as compared to the proposed project.
- Alternative 4 is not responsive to changes in planning assumptions and could result in unfair distribution of burden for reducing emissions.
- Alternative 5 may not meet project objectives because a VMT metric may not translate directly into desired emission reductions.

Setting Regional Targets requires a balance between setting goals that are high enough to motivate a departure from business-as-usual planning and development, but not so high as to be out of reach of the regions and local governments. Setting targets too high negates the potential to reduce statewide emissions levels through reduced passenger vehicle travel. Setting targets too low leads to a similar outcome. This is why after months of extensive consultation with academic experts, MPOs, state agencies, local governments, and the public, staff concludes that the proposed Regional Targets are the most ambitious and achievable based on information available at this time, and result in the greatest environmental benefit, as compared to the alternatives described above. The proposed Regional Targets will foster the most change by challenging each region yet allowing them to be able to achieve the targets and take advantage of SB 375 incentives.

V. Conclusion

ARB staff has concluded that the subsequent actions of MPOs after ARB establishes Regional Targets may have adverse impacts on the environment. However, we cannot speculate at this time what those specific impacts may be, due to lack of sufficient information about the mix, location, and nature of those subsequent actions.

While there is a potential for adverse impacts based on subsequent regional and local decisions, the net benefit to the environment from minimizing long-term transportation-related greenhouse gas emissions is potentially substantial. SB 375 is designed to institutionalize an alternative approach to planning for new growth, at the state, regional and local levels. Over time, this approach will result in minimizing the impact of California's transportation-related greenhouse gas emissions. The cumulative impact of greenhouse gas reductions from SB 375 combined with reductions from sources both within and outside of California is intended to reduce the substantial environmental impacts of climate change.

In addition, ARB staff considered several alternatives to the proposed Regional Targets and concluded that the proposed project is preferred for minimizing adverse impacts to the environment while meeting the intent of SB 375 to achieve greenhouse gas reductions from the land use and transportation sector. This determination was reached only after staff:

- Consulted the Climate Change Scoping Plan Functional Equivalent Document;
- Thoroughly reviewed MPO RTPS, data, and scenario submittals;
- Determined that ARB cannot predict what land use, transportation, and other policy measures will be implemented by MPOs to achieve the regional targets in future RTP planning cycles;
- Recognized that each individual SCS would have to undergo a substantial environmental review as part of the RTP adoption process; and
- Concluded ARB's proposed action cannot interfere with local government land use decisions (Cal. Const. Art. 11 § 7, GC § 65080(b)(2)(K).

A 45-day public review period of this Functional Equivalent Document is provided pursuant to CEQA. ARB will respond to all significant environmental concerns raised by the public during this comment period or at the ARB Board Hearing prior to taking final action to establish Regional Targets.

Appendix C Calculation References

Converting to CO_2 Equivalent

To incorporate and evaluate non-CO_2 gases in your GHG emissions inventory, the mass estimates of these gases will need to be converted to CO_2 equivalent (CO_2e). To do this, multiply the emissions in units of mass by the GHGs global warming potential (GWP).

Global warming potentials were developed by the Intergovernmental Panel on Climate Change (IPCC) to quantify the globally averaged relative radiative forcing effects of a given GHG, using carbon dioxide as the reference gas. In 1996, the IPCC published a set of GWPs for the most commonly measured greenhouse gases in its Second Assessment Report (SAR). In 2001, the IPCC published its Third Assessment Report (TAR), which adjusted the GWPs to reflect new information on atmospheric lifetimes and an improved calculation of the radiative forcing of carbon dioxide. However, SAR GWPs are still used by international convention and the U.S. to maintain the value of the carbon dioxide "currency". To maintain consistency with international practice, the California Registry requires participants to use GWPs from the SAR for calculating their emissions inventory.

Table C.1 lists the 100-year GWPs from SAR and TAR. The equation above provides the basic calculation required to determine CO_2e from the total mass of a given GHG using the GWPs published by the IPCC.

Converting Mass Estimates to Carbon Dioxide Equivalent

Metric Tons of CO_2e = Metric Tons of GHG x GWP

Table C.1 Comparison of GWPs from the IPCC's Second and Third Assessment Reports

Greenhouse Gas	GWP (SAR, 1996)	GWP (TAR, 2001)
CO_2	1	1
CH_4	21	23
N_2O	310	296

Note: Reporters calculating historical data for calendar years 1990-2007 should use the electricity emission factors in Appendix E.

III.7.6 Example: Carbon Dioxide Emissions from Biodiesel

BioClean Drycleaning Service

BioClean is an environmentally-friendly dry cleaning service with a delivery fleet of 10 biodiesel vans. Last year, the company purchased 12,000 gallons of B20 to fuel their vans.

Step 1: Identify the biodiesel blend being used.

BioClean is using B20, which is made up of 20% biodiesel and 80% petroleum-based diesel.

Step 2: Identify total annual biodiesel consumption.

BioClean purchased 12,000 gallons of B20 – they do not store fuel on-site, so no additional mass balance calculation is needed.

Step 3: Based on the blend, calculate the annual consumption of diesel and biodiesel.

Annual consumption of B20 = 12,000 gallons

12,000 gallons x 80% = 9,600 gallons diesel consumed

12,000 gallons x 20% = 2,400 gallons biodiesel consumed

Step 4: Select the appropriate emission factor for the petroleum-based diesel from Appendix C, Table C.3 to calculate the anthropogenic CO_2 emissions.

The CO_2 emission factor for diesel is 10.15 kilograms per gallon, and the biogenic CO_2 emission factor for biodiesel is 9.46 kilograms per gallon.

Carbon Dioxide Emission Factors for Transport Fuels

Fuel	kg CO_2/gallon
Diesel	10.15
Biodiesel (B100)	9.46*

* Note that the CO_2 emissions from burning biodiesel are biogenic, and should not be included as direct mobile emissions in your inventory. These emissions may be reported optionally.

Step 5: Multiply fuel consumed by the emission factor to calculate total CO_2 emissions and convert to metric tons.

Equation III.7c	CO_2 Emissions Contribution of Each Fuel							
CO_2 from diesel	=	10.15 kg/gallon	x	9,600 gallons	x	0.001 metric tons/kg	=	97.44 metric tons CO_2
Biogenic CO_2 from biodiesel	=	9.46 kg/gallon	x	2,400 gallons	x	0.001 metric tons/kg	=	22.70 metric tons biogenic CO_2

III.6.3 Example: Indirect Emissions from Electricity Use

Costlo Clothing Distributors

Costlo is a discount retail clothing chain with two outlets in Los Angeles, California, one in Portland, Oregon, and one in Tucson, Arizona. The company only purchases electricity and has no other GHG emissions.

Step 1: Determine annual electricity consumption.

Step 2: Select electricity emission factors that apply to the electricity purchased.

Because emission factors for electricity vary from region-to-region, Costlo tracks its electricity purchases by utility providing the electricity.

Annual Electricity Emissions and Emissions Factors

Region/ State	Power Generator	Annual Electricity Purchases (MWh)	CO_2 lbs/MWh	CH_4 lbs/MWh	N_2O lbs/MWh
CAMX/ California	Los Angeles	1,600	724.12	0.0302	0.0081
NWPP/Oregon	Portland	600	902.24	0.0191	0.0149
AZNM/Arizona	Tucson	800	1,311.05	0.0175	0.0179

Step 3: Determine total annual emissions and convert to metric tons.

Equation III.6b	Total Carbon Dioxide, Methane, and Nitrous Oxide Emissions for Electricity Use from Each Utility							
Los Angeles, CA	=	1,600 MWh	x	724.12 (lbs/MWh)	÷	2,204.62 lbs/mt	=	525.53 mt CO_2
Portland, OR	=	600 MWh	x	902.24 (lbs/MWh)	÷	2,204.62 lbs/mt	=	245.55 mt CO_2
Tucson, AZ	=	800 MWh	x	1,311.05 (lbs/MWh)	÷	2,204.62 lbs/mt	=	475.75 mt CO_2
						Subtotal	=	1,246.83 mt CO_2
Los Angeles, CA	=	1,600 MWh	x	0.0081 (lbs/MWh)	÷	2,204.62 lbs/mt	=	0.00588 mt N_2O
Portland, OR	=	600 MWh	x	0.0149 (lbs/MWh)	÷	2,204.62 lbs/mt	=	0.00406 mt N_2O
Tucson, AZ	=	800 MWh	x	0.0179 (lbs/MWh)	÷	2,204.62 lbs/mt	=	0.00650 mt N_2O
						Subtotal	=	0.01644 mt N_2O
Los Angeles, CA	=	1,600 MWh	x	0.0302 (lbs/MWh)	÷	2,204.62 lbs/mt	=	0.02192 mt CH_4
Portland, OR	=	600 MWh	x	0.0191 (lbs/MWh)	÷	2,204.62 lbs/mt	=	0.00520 mt CH_4
Tucson, AZ	=	800 MWh	x	0.0175 (lbs/MWh)	÷	2,204.62 lbs/mt	=	0.00635 mt CH_4
						Subtotal	=	0.03347 mt CH_4

Step 4: Convert Non-CO_2 emissions to CO_2e and sum the total. Use Equation III.6c and III.6d.

Equation III.6c	Convert Non-CO_2 GHGs to Carbon Dioxide Equivalent and Sum Total					
Metric Tons of CO_2e	=	Metric Tons of GHG	x	GWP (SAR, 1996)		
Metric Tons of CO_2					=	1,246.83 metric tons CO_2
CH_4 Tons of CO_2e	=	0.03347 metric tons CH_4	x	21 (GWP)	=	0.70287 metric tons CO_2e
N_2O Tons of CO_2e	=	0.01644 metric tons N_2O	x	310 (GWP)	=	5.0964 metric tons CO_2e
				Total	=	1,252.63 metric tons CO_2e

GLOBAL CLIMATE CHANGE AND CALIFORNIA

In Support of the *2005 Integrated Energy Policy Report*

California Energy Commission

STAFF FINAL PAPER

DISCLAIMER

This paper was prepared as the result of work by a member of the staff of the California Energy Commission. The paper has been revised from an earlier version to reflect 2002 data now available for the statewide emissions inventory. It does not necessarily represent the views of the Energy Commission, its employees, or the State of California. The Energy Commission, the State of California, its employees, contractors and subcontractors make no warrant, express or implied, and assume no legal liability for the information in this paper; nor does any party represent that the uses of this information will not infringe upon privately owned rights. This paper has not been approved or disapproved by the California Energy Commission nor has the California Energy Commission passed upon the accuracy or adequacy of the information in this paper.

June 2005
CEC-600-2005-007-SF

their GHG emissions, pledging to reduce emission levels to five percent below 1990 levels by 2012.[5]

In its December 2004 Report to the Congress, the National Commission on Energy recommended that the United States establish a mandatory, economy-wide trading system to curb the nation's increasing GHG emissions, and that the United States should join efforts with other countries to reduce global GHG emissions.[6]

The Intergovernmental Panel on Climate Change (IPCC), an international scientific body which periodically assesses the state of the climate change science, found in 2000 that "there is new and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities."[7]

In May 2001, President George W. Bush asked the National Academy of Science (NAS) to assess the veracity of the IPCC findings. According to the NAS, the IPCC assessment "accurately reflects the current thinking of the scientific community on this issue." In addition, the NAS reported that "GHG are accumulating in Earth's atmosphere as a result of human activities, causing surface air temperatures and subsurface ocean temperatures to rise. Temperatures are, in fact, rising." [8]

A 2004 study by a team of leading California scientists, *Climate Change in California: Choosing Our Future*, predicts substantial increases in temperatures in both the summer and winter months as a result of climate change.[9] Using scenarios of lower and higher future emissions, and state-of-the-art climate models, the authors report significant changes in California's natural resources could result, including:

- Rising sea levels along the California coastline, especially in San Francisco and the San Joaquin Delta.

- Extreme-heat conditions, such as heat waves and very high temperatures, which will last longer and become more commonplace.

- An increase in heat-related human deaths, infectious diseases and a higher risk of respiratory problems caused by deteriorating air quality.

- Reduced snow pack and stream flow in the Sierra Nevada Mountains, affecting winter recreation and water supplies.

- Rising temperatures that can affect California agriculture, causing variations in crop quality and yield.

- Changes in the distribution of vegetation from projected increases in temperature and high fire risk.

These changes in California's climate and ecosystems are occurring at a time when the state's population is projected to grow from 34 million people to 59 million by the year 2040. Population growth and the demand for vital natural resources will compound the effects of climate change on water resources, human health and the environment.

Purpose of the Paper

This paper builds upon prior work carried out in numerous public forums, including the *2003 Integrated Energy Policy Report (Energy Report),* the *2004 Energy Report Update*, the California Climate Action Registry, the California Public Utilities Commission (CPUC) decisions related to climate change, and the California Energy Commission's (Energy Commission) Climate Change Advisory Committee. The paper also highlights coordinated efforts by state government agencies to address global climate change through the Joint Agency Climate Team in California, the West Coast Governors' Global Warming Initiative, and the Regional GHG Initiative in the Northeastern and Mid-Atlantic states.

This paper provides background and context to guide the formulation of policy options for reducing GHG emissions in California. Following a summary of state legislation on global climate change, the paper discusses the science of climate change, the impacts of climate change on California, emerging trends in GHG emissions, existing state policies and programs, options for addressing climate change, and recommended next steps.

Legislative Background

In 1988, the California Legislature first recognized the potential adverse effects of climate change when it enacted a state law [AB 4420 (Sher), Chapter 1506, Statutes of 1988] directing the Energy Commission to assess the impacts of climate change on energy supply and demand as well as the state's economy, environment, agriculture, and water supplies. The law also directed the Energy Commission to identify potential GHG reducing strategies. In response, the Energy Commission published *"Global Climate Change: Potential Impacts and Policy Recommendations"* in December, 1991.

Since then, numerous statutes have been enacted that have shaped California's climate change policies and programs. In 2004, the Legislature enacted budget control language which gave authority to the Secretary for Environmental Protection to coordinate greenhouse gas emission reductions and climate change activity in state government. (SB 1107, Chapter 230, Statutes of 2004)

CALIFORNIA ENERGY COMMISSION

INVENTORY OF CALIFORNIA GREENHOUSE GAS EMISSIONS AND SINKS: 1990 TO 2004

STAFF FINAL REPORT

December 2006
CEC-600-2006-013-SF

Arnold Schwarzenegger, *Governor*

EXECUTIVE SUMMARY

This report updates California's statewide inventory of greenhouse gas (GHG) emissions to support evaluation of state policies that address climate change and climate variability or more commonly known as global warming. Information in this report extends the inventory period through 2004, which is the most recent year that data are available from the California Energy Commission (Energy Commission) or the United States Department of Energy's (DOE's) Energy Information Administration. This inventory reports GHG emissions from out-of-state electricity used in California along with in-state generation GHG emissions and estimates future emissions trends using fuel demand and other forecast data from the Energy Commission's *2005 Integrated Energy Policy Report*.

California's economy experienced the second largest percentage growth in terms of gross state product (in dollars, not adjusted for inflation) of any state in the country from 1990 to 2003.[1] During that period, California's GSP grew 83 percent while its GHG emissions grew more slowly at 12 percent. This demonstrates the potential for uncoupling economic trends from GHG emissions trends.

Nonetheless, California's GHG emissions are large and growing. As the second largest emitter of GHG emissions in the United States and twelfth to sixteenth largest in the world,[2] the state contributes a significant quantity of GHGs to the atmosphere.

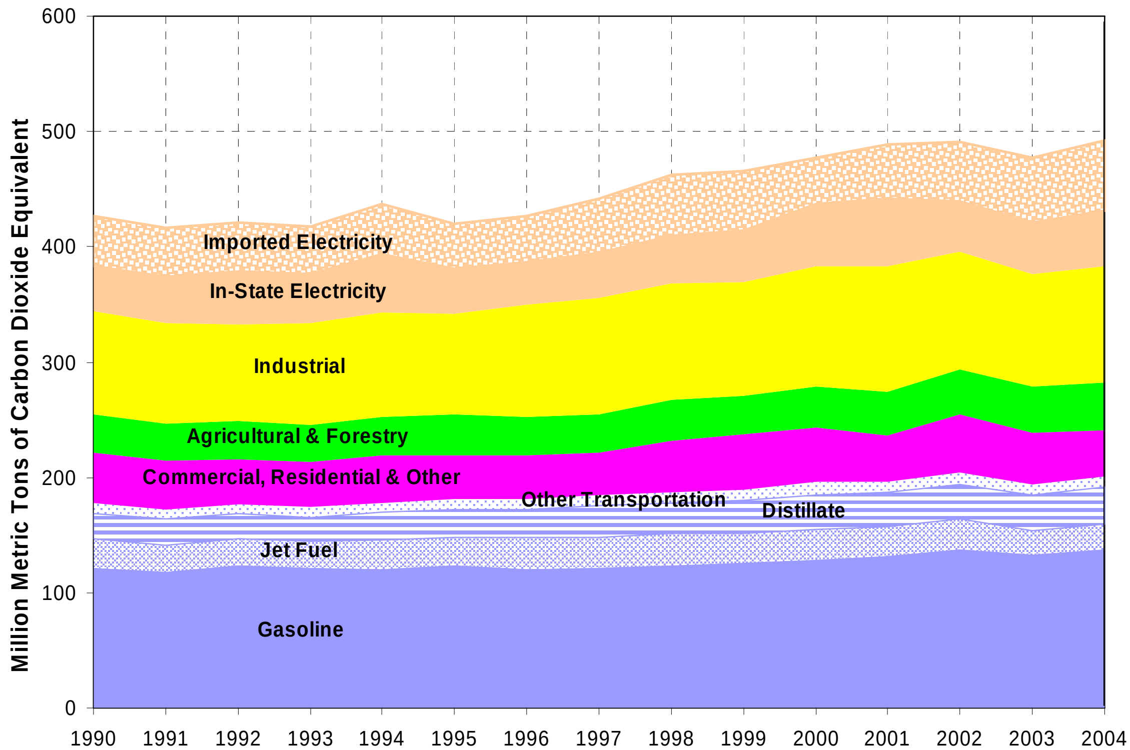
California's ability to slow the rate of growth of GHG emissions is largely due to the success of its energy efficiency and renewable energy programs and a commitment to clean air and clean energy. In fact, the state's programs and commitments lowered its GHG emissions rate of growth by more than half of what it would have been otherwise.[3] Moreover, California's energy programs and policies have had multiple benefits that include not only reducing GHG emissions, but reducing energy demand and improving air quality and public health.

Although California's total GHG emissions are larger than every state but Texas, California has relatively low carbon emission intensity. In 2001, California ranked fourth lowest of the 50 states in carbon dioxide emissions per capita from fossil fuel combustion and fifth lowest of the 50 states in carbon dioxide emissions from fossil fuel combustion per unit of gross state product. Emission trends per unit of gross state product are encouraging; most states have reduced their emissions per unit of gross state product over the 1990 to 2001 period.

In 2004, California produced 492 million gross metric tons of carbon dioxide-equivalent[4] GHG emissions, including imported electricity and excluding combustion of international fuels and carbon sinks or storage.

Figure 1 shows year-by-year trends in GHG emissions for the major energy sectors. Values differ yearly due to changes in fuel uses, meteorological variations, and other factors.

Figure 1 -- California's Gross GHG Emissions Trends



Source: California Energy Commission

The transportation sector is the single largest category of California's GHG emissions, producing 41 percent of the state's total emissions in 2004. Most of California's emissions, 81 percent, are carbon dioxide produced from fossil fuel combustion.

This California GHG emissions inventory excludes all international fuel uses, reporting them separately. Including these international emissions would increase total emissions by 27 to 40 million metric tons of carbon dioxide–equivalent GHG emissions, depending on the year.

Electricity generation is the second largest category of GHG emissions (behind transportation). In particular, out-of-state electricity generation has higher carbon intensity than in-state generation. While imported electricity is a relatively small methods being used by the EPA. An update[21] to this inventory was prepared and published in June 2005 to incorporate newer information and to allow policy makers to use the most current information and data available.

Summary of California's 2004 GHG Emissions

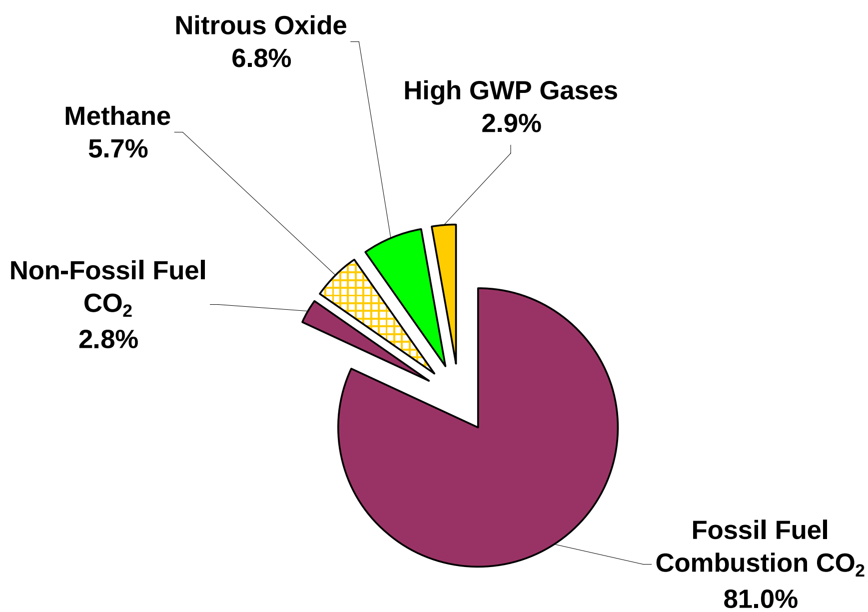
In 2004 California produced 492 million metric tons of CO_2-equivalent GHG emissions, including emissions associated with imported electricity. As shown in Figure 2, 81 percent were emissions of CO_2 from fossil fuel combustion, 2.8 percent were from other sources of CO_2, 5.7 percent were from methane, and 6.8 percent were from nitrous oxide. The remaining source of GHG emissions was high GWP gases, 2.9 percent.

The percentage of climate change associated with each specific gas is similar for each year over the 1990 to 2004 period. However, high GWP gas percentages are rising somewhat.

Composition of California's GHG Emissions

CO_2 emissions represent about 84 percent of California's total GHG emissions in 2004. CO_2 emissions are mainly associated with carbon-bearing fossil fuel combustion with a portion of these emissions attributed to out-of-state fossil fuel used for electricity consumption within California. Other activities that produce CO_2 emissions include mineral production, waste combustion, and land use and forestry changes. Some anthropogenic activities lead to a reduction in atmospheric concentration of CO_2. These are called "CO_2 sinks."

Figure 2 -- California GHG Composition by Type of Gas in 2004
(Includes electricity imports and excludes international bunker fuels)



Source: California Energy Commission

Methane emissions also contribute to global warming and they represented 5.7 percent of total GHG emissions in 2004. Methane emissions are reported in CO_2-equivalent units to reflect their GWP compared to CO_2. Agricultural activities (enteric fermentation and manure management) and landfills compose the major sources of these emissions.

Another gas that contributes to global warming is nitrous oxide (N_2O). Agricultural soil management activities and mobile source fuel combustion compose the major sources of these emissions. After using the appropriate GWP adjustment, N_2O emissions comprised 6.8 percent of California's overall GHG emissions in 2004.

A class of gases called "high GWP gases" makes up the final set of gases that contribute to global warming,[22] composing about 2.9 percent of total emissions in 2004. These are composed mostly of gases used in industrial applications to replace gases associated with ozone depletion over the Earth with an additional modest contribution from sulfur hexafluoride (SF_6) used as insulating materials in electricity transmission and distribution.

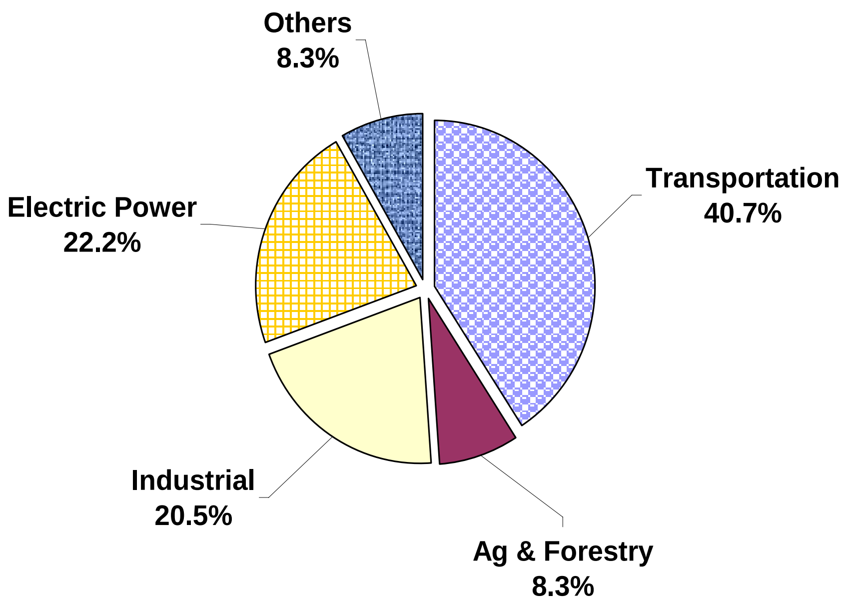
High GWP gases compose a low percentage of overall GHG emissions over this time period, although the estimated emissions are difficult to quantify and are less certain than other emissions categories. Although small in magnitude, emissions of these gases are increasing at a faster rate than other GHGs. In California, high GWP gases are largely composed of refrigerants, although electric utility transmission and distribution equipment are also sources.

End-Use Sectors Contributing to California's GHG Emissions

As shown in Figure 3, fossil fuel consumption in the transportation[23] sector was the single largest source of California's GHG emissions in 2004, with electric power from both in-state and out-of-state sources second, and the industrial[24] sector as the third largest source category. Agriculture,[25] forestry,[26] commercial,[27] and residential[28] activities composed the balance of California's GHG emissions.

Care must be exercised when looking at emissions from different sectors of the economy. For example, the GHG inventory identifies cement production from clinker manufacturing in a stand-alone category and fuel used to heat the cement production process within the industrial fuel category. Thus, CO_2 from clinker production does not represent total GHG emissions from cement production. Likewise, the GHG inventory reports landfill methane emissions in the methane portion of the inventory and CO_2 sinks associated with landfills in the CO_2 portion of the inventory. Taken together, the landfill CO_2 sinks approximately offset the landfill methane emissions. However, there are additional fuel related GHG emissions from transporting wastes to landfills, and these emissions are included in transportation fuels.

Figure 3 -- Sources of California's 2004 GHG Emissions (By End-Use Sector) (Includes electricity imports and excludes international bunker fuels)



Source: California Energy Commission

Historical GHG Emissions Trends

This section discusses historical trends in California's gross GHG emissions. The values discussed in this section do not account for CO_2 sinks from forest, rangelands, or landfill and yard trimming disposal.

This section also excludes international aviation and marine vessel uses of jet fuel, residual oil,[29] and distillate oil because they are international fuel uses and the standard GHG emissions inventory protocol excludes them. Domestic aviation gasoline, jet fuel, residual oil, and distillate oil uses are included in the analysis.

The trends discussed in this section include carbon emissions from imported electricity, including out-of-state coal-fired power plants owned by California electric utility companies that provide electricity to California.

California's GHG emissions are large and growing as a result of population and economic growth and other factors. From 1990 to 2004 total gross GHG emissions rose 14.3 percent; they are expected to continue to increase in the future under "business-as-usual" unless California implements programs to reduce emissions.

REFINING ESTIMATES OF WATER-RELATED ENERGY USE IN CALIFORNIA

PIER FINAL PROJECT REPORT

Prepared For:

California Energy Commission
Public Interest Energy Research Program

Prepared By:
Navigant Consulting, Inc.

NAVIGANT CONSULTING

December 2006
CEC-500-2006-118

(MG) of water, and the number of kWh needed to treat and dispose of the same quantity of wastewater.

Inasmuch as water-energy is a new area of study, data were not readily available that directly related energy use to portions of the water-use cycle. Consequently, the team adjusted the existing data sets to prepare refined estimates.

Project Outcomes

Through detailed reviews of work papers and interviews with stakeholders, the study team identified a number of recommended adjustments to the water-energy relationship proxies for energy embedded in water for Northern and Southern California. Some of the recommended adjustments addressed a number of minor errors and inconsistencies in allocations made during the preparation of the WER. Others addressed adjustments needed to ensure consistency. In addition, the team recommends adjusting the estimates by segment of the water-use cycle for losses.

The type of water use determines whether wastewater treatment and disposal will be required. In general, outdoor water use, such as landscape irrigation, typically either flows into storm drains or recharges groundwater or natural waterways, bypassing need for wastewater treatment and disposal. Indoor water use typically discharges to sanitary sewers, consuming energy for wastewater treatment and disposal. To simplify application of the proxies, we recommend further breaking down the northern and southern proxies into indoor and outdoor use.

Table ES-1. Recommended revised water-energy proxies

	Indoor Uses		Outdoor Uses	
	Northern California kWh/MG	Southern California kWh/MG	Northern California kWh/MG	Southern California kWh/MG
Water Supply and Conveyance	2,117	9,727	2,117	9,727
Water Treatment	111	111	111	111
Water Distribution	1,272	1,272	1,272	1,272
Wastewater Treatment	1,911	1,911	0	0
Regional Total	5,411	13,022	3,500	11,111

The bases for the recommended adjustments are provided in Section 2 and the appendices to this report.

California Energy Consumption Database

The California Energy Commission has created this on-line database for informal reporting purposes using numerous electricity and natural gas consumption data sources.

Users can generate reports showing the amount of energy consumed by geographical area, sector (residential, commercial, industrial) classifications. The database also provides easy downloading of energy consumption data into Microsoft Excel (XLS) and comma-separated values (CSV) file formats.

For further information about, or problems with this database, please contact Steven Mac at steven.mac@energy.state.ca.us or call 916-651-1468. Members of the news media please call the Media and Public Communications Office at 916-654-4989.

Version 3.0

September 1, 2009

The derived estimate of biomass must be multiplied by 0.5 to calculate the mass (kg) in carbon. This product must be multiplied by 0.001 tonnes/kg to convert the mass to metric tonnes of carbon.

Because of the difficulties associated with measuring the below-ground carbon component of trees, the Reserve allows for the estimation of this component of tree carbon through the use of a regression equation (Cairns, Brown, Helmer, & Baumgardner, 1997). This equation provides a practical and cost-effective approach that estimates below-ground biomass of standing live trees using the sampling-based calculation of above-ground biomass of standing live trees only:

$$BBD = \exp(-0.7747 + 0.8836 * \ln(ABD))$$

Where:

BBD = below-ground biomass density of standing live trees in tonnes per hectare
ABD = above-ground biomass density of standing live trees in tonnes per hectare

This equation must be applied at the plot level, after estimates of above-ground biomass have been calculated as described above.

Example A.1. Quantification Example (Part III – Tree Biomass)

The chart below displays summary data for tree biomass for the first plot in Strata 1.

Tree Biomass								
1	2	3	4	5	6	7	8	9
Plot	Tree Number	Species	DBH (cm)	Total Height (m)	Status	Biomass (kg)	Weight (Expansion per Hectare)	Biomass (kg per Hectare)
1	1	Redwood	65	32	L	2,560	21	53,768
1	2	Douglas-fir	65	29	L	2,007	21	42,152
1	3	Tanoak	28	14	L	280	112	31,402
1	4	Redwood	68	30	L	2,677	19	50,858
1	5	Redwood	76	27	L	3,086	15	46,287
1	6	Douglas-fir	65	34	L	2,310	21	48,501
1	7	Tanoak	42	17	L	729	50	36,442
1	8	Tanoak	46	18	L	914	41	37,464
							Total	346,874

The plot in this example was measured using a 30 square foot basal area factor prism. The plot number is entered in column 1. All ‘in’ trees (trees on the plot) are measured and input consecutively starting at North and proceeding clockwise (this facilitates check cruising, quality control). Each tree is numbered (column 2), the species documented (column 3), the DBH measurements entered as centimeters in column 4, and the total height entered as meters in column 5.

The status of the tree goes in column 6. The status codes are shown below.

Once all emission reductions are scaled by their applicable sector and land use, they should be added together for the total sum of emission reductions.

The following tables list feasible mitigation measures for consideration in projects. The estimated emission reductions are a work in progress and the Air District will continue to improve guidance on quantifying the mitigation measures.

URBEMIS Mitigation Measures for Operational Mobile Source Emissions

Measure	Sector Reductions	Applicable Pollutants	Sector	Notes	Additional comments
Mix of Uses	-3% to 9%	CAPs, GHGs	Mobile sources	-3 when no housing or employment centers within 1/2 mile	Residential: % reduction is taken from base trips (9.57) and subtracted from ITE trip generation; Nonresidential: % reduction from ITE trip generation
Local serving retail within 1/2 mile of project	2%	CAPs, GHGs	Mobile sources	Uses lower end of reported research to avoid double counting with mix of uses measure	
Transit Service	0% to 15%	CAPs, GHGs	Mobile sources		
Bike & Pedestrian	0%–9%	CAPs, GHGs	Mobile sources	Credit is given based on intersection density, sidewalk completeness, and bike network completeness; No reduction if entire area within 1/2 mile is single use	
Affordable Housing	0%–4%	CAPs, GHGs	Mobile sources

Report #: DOE/EIA-0573(2007)
Released Date: December 3, 2008
Next Release Date: December 2009
Previous reports

Overview

Total Emissions

- Total U.S. greenhouse gas emissions in 2007 were 1.4 percent above the 2006 total.
- Total emissions growth—from 7,179.7 million metric tons carbon dioxide equivalent ($MMTCO_2e$) in 2006 to 7,282.4 $MMTCO_2e$ in 2007—was largely the result of a 75.9-$MMTCO_2e$ increase in carbon dioxide (CO_2) emissions. There were larger percentage increases in emissions of other greenhouse gases, but their absolute contributions to total emissions growth were relatively small: 13.0 $MMTCO_2e$ for methane (CH_4), 8.2 $MMTCO_2e$ for nitrous oxide, and 5.6 $MMTCO_2e$ for the man-made gases with high global warming potentials (high-GWP gases) (Table 1 below).
- The increase in U.S. carbon dioxide emissions in 2007 resulted primarily from two factors: unfavorable weather conditions, which increased demand for heating and cooling in buildings; and a drop in hydropower availability that led to greater reliance on fossil energy sources (coal and natural gas) for electricity generation, increasing the carbon intensity of the power supply.
- Methane emissions totaled 699.9 $MMTCO_2e$ in 2007 (Figure 1 at right), up by 13.0 $MMTCO_2e$ from 2006, with increases in emissions from energy sources, waste management, and agriculture.
- U.S. emissions of high-GWP gases, which totaled 176.9 $MMTCO_2e$ in 2007, were 5.6 $MMTCO_2e$ above the 2006 total. The increase resulted mainly from higher emissions levels for hydrofluorocarbons (HFCs, up by 4.1 $MMTCO_2e$) and perfluorocarbons (PFCs, up by 2.0 $MMTCO_2e$). Emissions of sulfur hexafluoride (SF_6) were down by 0.5 $MMTCO_2e$.

(Percent)		*15.0%*	*16.7%*
Average Annual Change from 1990 *(Percent)*		*0.9%*	*0.9%*
Change from 2006 (Million Metric Tons CO_2e)			102.7
(Percent)			*1.4%*

Greenhouse Gas Intensity

- From 2006 to 2007, the greenhouse gas intensity of the U.S. economy—measured as metric tons carbon dioxide equivalent ($MTCO_2e$) emitted per million dollars of gross domestic product (GDP)—fell by 0.6 percent, the smallest annual decrease since 2002.
- Economic growth of 2.0 percent in 2007, coupled with a 1.4-percent increase in total greenhouse gas emissions, accounted for the relatively slow rate of decrease (improvement) in U.S. greenhouse gas intensity from 2006 to 2007 (Table 2 below).
- Since 2002, the base year for the Bush Administration's emissions intensity reduction goal of 18 percent in a decade, U.S. greenhouse gas intensity has fallen by an average of 2.1 percent per year, resulting in a total reduction of 9.8 percent from 2002 to 2007.
- The steady decrease in carbon intensity (carbon/GDP) has resulted mainly from reductions in energy use per unit of GDP (energy/GDP) rather than increased use of low-carbon fuels, as indicated by the carbon/energy ratio shown in Figure 2 at right.

Figure 2. Intensity Ratios: Carbon/Energy, Energy/GDP, and Carbon/GDP, 1980-2007

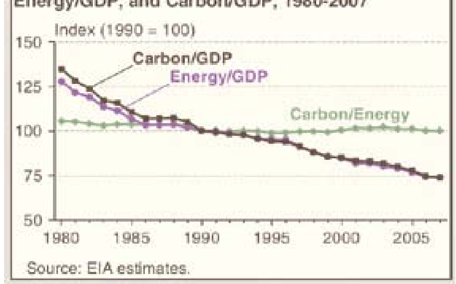

figure data

Table 2. U.S. Greenhouse Gas Intensity and Related Factors, 1990, 1995, and 2000-2007

	1990	1995	2000	2001	2002	2003	2004	2005	2006	P2007
Gross Domestic Product (Billion 2000 Dollars)	7,112.5	8,031.7	9,817.0	9,890.7	10,048.8	10,301.0	10,675.8	10,989.5	11,294.8	11,523.9
Greenhouse Gas Emissions ($MMTCO_2e$)	6,241.8	6,575.2	7,074.9	6,957.7	7,043.7	7,098.8	7,230.1	7,257.0	7,179.8	7,282.5
Greenhouse Gas Intensity ($MTCO_2e$ per Million 2000 Dollars)	877.6	818.7	720.7	703.5	701.0	689.1	677.2	660.4	635.7	631.9
Change from Previous Year (Percent)										
Gross Domestic Product	—	2.5	3.7	0.8	1.6	2.5	3.6	2.9	2.8	2.0
Greenhouse Gas Emissions	—	0.8	2.6	-1.7	1.2	0.8	1.8	0.4	-1.1	1.4
Greenhouse Gas Intensity	—	-1.7	-1.0	-2.4	-0.4	-1.7	-1.7	-2.5	-3.7	-0.6
Change from 2002 (Percent)[a]										
Cumulative	—	—	—	—	—	-1.7	-3.4	-5.8	-9.3	-9.8
Annual Average	—	—	—	—	—	-1.7	-1.7	-2.0	-2.4	-2.1

[a]The Bush Administration s emissions intensity goal calls for an 18-percent reduction between 2002 and 2012; achieving that goal would require an average annual reduction of slightly less than 2 percent over the entire period.

P = preliminary data.

Note: Data in this table are revised from the data contained in the previous EIA report, *Emissions of Greenhouse Gases in the United States 2006*, DOE/EIA-0573(2006) (Washington, DC, November 2007).

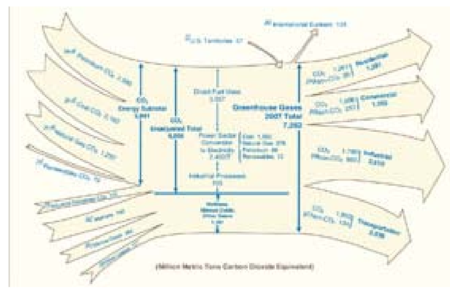
Data for all years 1990-2007

Greenhouse Gas Emissions in the U.S. Economy

The diagram on the right illustrates the flow of U.S. greenhouse gas emissions in 2007, from their sources to their distribution across the U.S. end-use sectors. The left side shows CO_2 by fuel sources and quantities and other gases by quantities; the right side shows their distribution by sector. The center of the diagram indicates the split between CO_2 emissions from direct fuel combustion and electricity conversion. Adjustments indicated at the top of the diagram for U.S. territories and international bunker fuels correspond to greenhouse gas reporting requirements developed by the United Nations Framework Convention on Climate Change (UNFCCC).



Click Chart to Enlarge

CO_2. CO_2 emission sources include energy-related emissions (primarily from fossil fuel combustion) and emissions from industrial processes. The energy subtotal (5,991 $MMTCO_2e$) includes petroleum, coal, and natural gas consumption and smaller amounts from renewable sources, including municipal solid waste and geothermal power generation. The energy subtotal also includes emissions from nonfuel uses of fossil fuels, mainly as inputs to other products. Industrial process emissions (105 $MMTCO_2e$) include cement manufacture, limestone and dolomite calcination, soda ash manufacture and consumption, carbon dioxide manufacture, and aluminum production. The sum of the energy subtotal and industrial processes equals unadjusted CO_2 emissions (6,096 $MMTCO_2e$). The energy component of unadjusted emissions can be divided into direct fuel use (3,557 $MMTCO_2e$) and fuel converted to electricity (2,433 $MMTCO_2e$).

Non-CO_2 Gases. Methane (700 $MMTCO_2e$) and nitrous oxide (384 $MMTCO_2e$) sources include emissions related to energy, agriculture, waste management, and industrial processes. Other, high-GWP gases (177 $MMTCO_2e$) include hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6). These gases have a variety of uses in the U.S. economy, including refrigerants, insulators, solvents, and aerosols; as etching, cleaning, and firefighting agents; and as cover gases in various manufacturing processes.

Adjustments. In keeping with the UNFCCC, CO_2 emissions from U.S. Territories (57 $MMTCO_2e$) are added to the U.S. total, and CO_2 emissions from fuels used for international transport (both oceangoing vessels and airplanes) (131 $MMTCO_2e$) are subtracted to derive total U.S. greenhouse gas emissions (7,282 $MMTCO_2e$).

Emissions by End-Use Sector. CO_2 emissions by end-use sectors are based on EIA's estimates of energy consumption (direct fuel use and purchased electricity) by sector and on the attribution of industrial process emissions by sector. CO_2 emissions from purchased electricity are allocated to the end-use sectors based on their shares of total electricity sales. Non-CO_2 gases are allocated by direct emissions in those sectors plus emissions in the electric power sector that can be attributed to the end-use sectors based on electricity sales.

Residential emissions (1,281 $MMTCO_2e$) include energy-related CO_2 emissions (1,261 $MMTCO_2e$); and non-CO_2 emissions (20 $MMTCO_2e$). The non-CO_2 sources include direct methane and nitrous oxide emissions from direct fuel use. Non-CO_2 indirect emissions attributable to purchased electricity, including methane and nitrous oxide emissions from electric power generation and SF_6 emissions related to electricity transmission and distribution, are also included.

Emissions in the commercial sector (1,355 $MMTCO_2e$) include both energy-related CO_2 emissions (1,098 $MMTCO_2e$) and non-CO_2 emissions (257 $MMTCO_2e$). The non-CO_2 emissions include direct emissions from landfills, wastewater treatment plants, commercial refrigerants, and stationary combustion emissions of methane and nitrous oxide. Non-CO_2 indirect emissions attributable to purchased electricity, including methane and nitrous oxide emissions from electric power generation and SF_6 emissions related to electricity transmission and distribution, are also included.

Industrial emissions (2,610 $MMTCO_2e$) include CO_2 emissions (1,760 $MMTCO_2e$)—which can be broken down between combustion (1,655 $MMTCO_2e$) and process emissions (105 $MMTCO_2e$)—and non-CO_2 emissions (850 $MMTCO_2e$). The non-CO_2 direct emissions include emissions from agriculture (methane and nitrous oxide), coal mines (methane), petroleum and natural gas pipelines (methane), industrial process emissions (methane, nitrous oxide, HFCs, PFCs and SF_6), and direct stationary combustion emissions of methane and nitrous oxide. Non-CO_2 indirect emissions attributable to purchased electricity, including methane and nitrous oxide emissions from electric power generation and SF_6 emissions related to electricity transmission and distribution, are also included.

Transportation emissions (2,036 $MMTCO_2e$) include energy-related CO_2 emissions from mobile source combustion (1,902 $MMTCO_2e$); and non-CO_2 emissions (134 $MMTCO_2e$). The non-CO_2 emissions include methane and nitrous oxide emissions from mobile source combustion and HFC emissions from the use of refrigerants for mobile source air-conditioning units.

Distribution of Total U.S. Greenhouse Gas Emissions by End-Use Sector, 2007

Greenhouse Gas and Source	Sector				
	Residential	Commercial	Industrial	Transportation	Total
	Million Metric Tons Carbon Dioxide Equivalent

U.S. Emissions in a Global Perspective

- In EIA's 2006 emissions inventory report, total U.S. energy-related carbon dioxide emissions in 2005 (including nonfuel uses of fossil fuels) were estimated at 5,982 MMT. With the 2005 world total for energy-related carbon dioxide emissions estimated at 28,051 MMT, U.S. emissions were about 21 percent of the world total (see Table 3 below).
- Carbon dioxide emissions related to energy use in the mature economies of countries that are members of the Organization for Economic Cooperation and Development (OECD)—including OECD North America, OECD Europe, Japan, and Australia/New Zealand—are estimated at 13,565 MMT, or 48 percent of the world total. With the remaining 52 percent of worldwide energy-related carbon dioxide emissions (14,486 MMT) estimated as having come from non-OECD countries, 2005 marked the first year in which emissions from the non-OECD economies were significantly greater than those from the OECD economies (Figure 3 at right).
- In EIA's *International Energy Outlook 2008* (*IEO2008*) reference case, projections of energy use and emissions

World Energy-Related Carbon Dioxide Emissions, 1990, 2005, and 2030

	1990	2005	2030*
Estimated Emissions (Million Metric Tons)	21,226	28,051	42,325
Change from 1990 (Million Metric Tons)		6,825	21,099
(Percent)		*32.2%*	*99.4%*
Average Annual Change from 1990 *(Percent)*		*1.9%*	*1.7%*
Change from 2005 (Million Metric Tons)			14,274
(Percent)			*50.9%*

*EIA, *International Energy Outlook 2008*.

are sensitive to economic growth rates and energy prices. Projections for a range of alternative growth and price scenarios are presented in *IEO2008*.

- U.S. energy-related carbon dioxide emissions are projected to increase at an average annual rate of 0.5 percent from 2005 to 2030 in the *IEO2008* reference case, while emissions from the non-OECD economies are projected to grow by 2.5 percent per year. As a result, the U.S. share of world carbon dioxide emissions is projected to fall to 16 percent in 2030 (6,851 MMT out of a global total of 42,325 MMT) (Figure 4 at right).
- China's share of global energy-related carbon dioxide emissions is projected to grow from 18 percent in 2005 to 28 percent in 2030. As a result, China is expected to be responsible for 47 percent of the projected increase in world emissions over the period. India is expected to account for the second-largest share of the projected increase, 8 percent.

Recent U.S. and International Developments in Global Climate Change

United States

- ***Federal Actions***
  The Consolidated Appropriations Act of 2008, which became Public Law 110-161 on December 26, 2007, directed the U.S. Environmental Protection Agency (EPA) to develop a draft mandatory reporting rule for greenhouse gases by the end of September 2008; although the draft rule has not yet been released, the Final Rule is due to be completed by June 2009. The Rule is expected to require mandatory reporting of greenhouse gas emissions "above appropriate thresholds in all sectors of the economy," with thresholds and frequency of reporting to be determined by the EPA.
- In July 2008, the EPA released an Advance Notice of Proposed Rulemaking (ANPR) to implement the ruling of the U.S. Supreme Court case, Massachusetts v. the Environmental Protection Agency. On April 2, 2007, the Court ruled that Section 202(a)(1) of the Clean Air Act (CAA) gives the EPA authority to regulate tailpipe emissions of greenhouse gases. Four key issues for discussion in the ANPR include: descriptions of key provisions and programs in the CAA and advantages and disadvantages of regulating greenhouse gases under those provisions; how a decision to regulate GHG emissions under one section of the CAA could or would lead to regulation of GHG emissions under other sections of the Act, including sections establishing permitting requirements for major stationary sources of air pollutants; issues relevant for Congress to consider for possible future climate legislation and the potential for overlap between future legislation and regulation under the existing CAA; and scientific information relevant to, and the issues raised by, an endangerment analysis.
- ***Congressional Initiatives***
  Senate Bill 3036, the Lieberman-Warner Climate Security Act of 2008, came to the floor for debate in the Senate on June 2, 2008. The main purpose of the Act was to establish a Federal program that would substantially reduce U.S. greenhouse gas emissions between 2007 and 2050, in large part through a Federal cap-and-trade program.
- ***Regional and State Efforts***
  On September 25, 2008, the Regional Greenhouse Gas Initiative (RGGI) held its first auction. More than 12.6 million tons were sold at a clearing price of $3.07. New York, with 40 percent allowance allocation, did not participate in the first round of auctions; however, all 10 States are expected to participate in the second allowance auction on December 17, 2008, at which 31.5 million allowances will be available with a reserve price set at $1.86. RGGI is a cooperative effort by 10 Northeast and Mid-Atlantic States to limit greenhouse gas emissions from the electric power sector. Connecticut, Delaware, Maine, Maryland, Massachusetts, New Hampshire, New Jersey, New York, Rhode Island, and Vermont are signatory States to the RGGI agreement.
- On September 28, 2008, the Western Climate Initiative (WCI) released a detailed scoping plan for its regional market-based cap-and-trade program. The multi-sector program will be the most comprehensive carbon reduction strategy to date, covering nearly 90 percent of the region's emissions, including those from electricity, industry, transportation, and residential and commercial fuel use, and reducing greenhouse gas emissions to 15 percent below 2005 levels by 2020. On September 30, 2008, the WCI released its Second Draft of Reporting Requirements, which addresses the essential requirements for mandatory reporting. Participating U.S. States include Arizona, California, Montana, New Mexico, Oregon, Utah, and Washington. Canadian provinces participating include British Columbia, Manitoba, Ontario, and Quebec.
- Nine Midwestern governors and two Canadian premiers signed on to participate or observe in the Midwestern Greenhouse Gas Reduction Accord as first agreed to in November 2007. Member States have agreed to reduce greenhouse gas emissions, and a working group is to provide recommendations regarding the implementation of the Accord. In September 2008, the Advisory Group released an updated timeline that requires preliminary design recommendations to be released by November 2008, final recommendations by March 2009, and a draft model rule between May and September 2009. Member States include Iowa, Illinois, Kansas, Michigan, Minnesota, and Wisconsin, as well as the Canadian province of Manitoba. Observer States include Indiana, Ohio, and South Dakota, as well as the Canadian province of Ontario.
- On September 30, 2008, Governor Arnold Schwarzenegger of California signed S.B. 375 to integrate greenhouse gas emissions into California's transportation planning decisions. Under the law, the California Air Resources Board will work with California's 18 metropolitan planning organizations to align their regional transportation, housing, and land-use plans and prepare a "sustainable communities strategy" to reduce vehicle-miles traveled in their respective areas and demonstrate the region's ability to meet its greenhouse gas reduction targets.[1]

International: United Nations Framework Convention on Climate Change and the Kyoto Protocol

COP-13 and CMP

In December 2007, the Thirteenth Conference of the Parties to the United Nation's Framework Convention on Climate Change (COP-13) and the Third Meeting of the Parties to the Kyoto Protocol (CMP-3) were held in Nusa Dua, Bali. Key areas included:

- Launch of a negotiating process with the expectation of reaching a comprehensive post-2012 agreement in 2009 (COP-13 and CMP-3)
- Agreement by developing countries to consider taking "measurable, reportable, and verifiable" mitigation actions, while receiving technological and financial support from developed countries (COP-13)
- Agreement by developed countries to consider making "commitments or actions, quantified emission limitation and reduction objectives," including making binding targets an option (COP-13)
- Reconstitution of the Expert Group on Technology Transfer for 5 more years, with a new mandate to evaluate technology transfer efforts and develop recommendations for strengthening the efforts in a post-2012 agreement (COP-13)
- Adoption of a decision encouraging countries with tropical forests to undertake demonstration activities, particularly the development of national emission baselines, and provide indicative guidance for such projects (COP-13)
- Setting of parameters for a thorough review of the Kyoto Protocol for CMP-4, including the scope and

effectiveness of the flexibility mechanisms, progress by developed countries in implementing their commitments on finance and technology for developing countries, and the possibility of extending to the other flexibility mechanisms the levy now applied to clean development mechanism (CDM) transactions to support the Protocol's Adaptation Fund(CMP-3)

- Resolution of long-standing differences on the governance of the Adaptation Fund, including establishing a 16-member Adaptation Fund Board to manage the fund on behalf of CMP (CMP-3).

COP-14 and CMP-4

Poland will host COP-14 and CMP-4 in Poznañ, December 1-12, 2008. Parties are expected to:

- Agree on a plan of action and programs of work for the final year of negotiations after a year of comprehensive and extensive discussions on crucial issues relating to future commitments, actions, and cooperation
- Make significant progress on several issues required to enhance further the implementation of the Convention and the Kyoto Protocol
- Advance understanding and commonality of views on a “shared vision” for a new climate change regime beyond the Kyoto Protocol
- Strengthen momentum and commitment to the process and the agreed timeline
- Discuss capacity-building for developing countries, reducing emissions from deforestation, and technology transfer and adaptation.

Units for Measuring Greenhouse Gases

Emissions data are reported here in metric units, as favored by the international scientific community. Metric tons are relatively intuitive for users of U.S. measurement units, because 1 metric ton is only about 10 percent heavier than a short ton.

Throughout this report, emissions of carbon dioxide and other greenhouse gases are given in carbon dioxide equivalents. In the case of carbon dioxide, emissions denominated in the molecular weight of the gas or in carbon dioxide equivalents are the same. Carbon dioxide equivalent data can be converted to carbon equivalents by multiplying by 12/44.

Emissions of other greenhouse gases (such as methane) can also be measured in carbon dioxide equivalent units by multiplying their emissions (in metric tons) by their global warming potentials (GWPs). Carbon dioxide equivalents are the amount of carbon dioxide by weight emitted into the atmosphere that would produce the same estimated radiative forcing as a given weight of another radiatively active gas.

Carbon dioxide equivalents are computed by multiplying the weight of the gas being measured (for example, methane) by its estimated GWP (which is 25 for methane). In 2007, the Intergovernmental Panel on Climate Change (IPCC) Working Group I released its Fourth Assessment Report, *Climate Change 2007: The Physical Science Basis*.[2] Among other things, the Fourth Assessment Report updated a number of the GWP estimates that appeared in the IPCC's Third Assessment Report.[3] The GWPs published in the Fourth Assessment Report were used for the calculation of carbon dioxide equivalent emissions for this report. Table 4 below summarizes the GWP values from the Second, Third, and fourth Assessment Reports.

Table 4. Greenhouse Gases and 100-Year Net Global Warming Potentials

Greenhouse Gas	Chemical Formula	Global Warming Potential

Methodology Updates for This Report

Carbon Dioxide

EIA has begun using a separate carbon coefficient for net imports of metallurgical coke, based on IPCC guidelines. The new coefficient more accurately reflects the carbon content of imported coke. The carbon in coke that is domestically produced, and the carbon dioxide emissions from that coke, are counted in the amount of domestic coking coal consumed. For net coke imports, however, it was decided that the new, higher carbon coefficient should be used. Although the difference between the two coefficients is about 14 percent, the amount of coke imported is relatively small. Thus, the increase in calculated carbon dioxide emissions resulting from the change in coefficients is in the range of 1 to 3 million metric tons for most years over the 1990-2007 period.

Estimates of carbon dioxide emissions from natural gas combustion have been adjusted upward, to reflect increasing concentrations of carbon dioxide in the natural gas produced in the United States in recent years. As a result of the change, the estimates of carbon dioxide emissions from natural gas combustion for recent years are about 1 million metric tons higher than those in last year’s report.

Because of a change in methodology, the estimate of carbon dioxide emissions from waste combustion (included in “Other Sources”) has been adjusted downward, as most of those emissions are accounted for by grid-connected waste-to-energy plants in the electric power sector, which are captured in EIA’s surveys. The result of this change is a reduction of 3 to 4 million metric tons per year from 1990 to 2007.

An error in the calculation code caused emissions from industrial lubricants to be omitted from total emissions in EIA’s emissions inventory reports for 2005 and 2006. Although lubricants are a nonfuel use, there are emissions associated with their use. Emissions from this source are again included in total emissions in this year’s report. As a result of the correction, the estimates of total U.S. carbon dioxide emissions are higher by about 6 to 7 million metric tons per year from 1990 to 2007 than those in the 2005 and 2006 data reports.

Other changes reflect revisions in the underlying activity data. For example, in the 2006 data report, the amount of natural gas consumed in the United States in 2005 was estimated at 22,241 billion cubic feet, whereas in this year’s report the estimate for 2005 is 22,011 billion cubic feet. As a result, the estimate for carbon dioxide emissions from natural gas combustion in 2005 is about 10 million metric tons lower in this year’s report than in last year’s report.

Methane

In its Fourth Assessment Report (AR4),[4] the IPCC developed revised global warming potential factors (GWPs) for selected gases. The GWP for methane was revised from the previously published value of 23 in the IPCC’s Third

Assessment Report[5] to 25 in the Fourth Assessment Report. The revised GWP for methane is used in this report. In addition, this report incorporates an increase in the density of methane from 42.28 to 42.37 pounds per thousand cubic feet, in order to provide consistent temperature and pressure values for methane in all EIA data.

Nitrous Oxide

The IPCC also updated the GWP for nitrous oxide in its Fourth Assessment Report, to 298, up from 296 in the IPCC's Third Assessment Report. The revised GWP for nitrous oxide is used in this report.

High-GWP Gases

The IPCC also updated GWPs for most of the high-GWP emissions sources in its Fourth Assessment Report. The revised GWPs are included in Table 4 on page 11, under "Units for Measuring Greenhouse Gases."

Land Use

Forest Land Remaining Forest Land is the major source of change in net carbon dioxide flux resulting from land use. In this report, the addition of newly available forest inventory data, as well as some refinements to previous data, involved the following major changes: incorporating and updating State and sub-State inventory data; and including a portion of Alaskan forest for the first time. In addition, minor refinements to the calculation of flux from harvested wood products included: a shorter half-life for decay in dumps; and separation of decay in dumps from decay in landfills. Overall, these changes, in combination with adjustments in the other sources/sinks within the land-use category, resulted in an average annual increase of 20.1 million metric tons carbon dioxide equivalent (2.5 percent) in net carbon flux to the atmosphere from Land Use, Land-Use Change, and Forestry for the years 1990 through 2005.

MEMORANDUM

Date: October 8, 2009

To: Rob Brueck, Hauge Brueck Associates, LLC

From: Katy Cole, P.E., Fehr & Peers
Marissa Harned, Fehr & Peers

SUBJECT: Homewood Mountain Resort Existing Volumes and Trip Generation

RN08-0403

This memorandum addresses the trip generation, pass-by, and internal capture rates used in the analysis of the Homewood Mountain Resort (HMR). A discussion of both the summer and winter trip generation is provided.

EXISTING HOMEWOOD VOLUMES

The existing HMR consists of a small, day-use ski resort that primarily serves locals of the Lake Tahoe area. No lodging is available on site, so skiers must arrive in the morning and leave at the end of the day. During the summer, HMR is not in operation on a regular basis.

The Friday PM peak hour was analyzed for the summer and winter seasons. During the summer, the Friday PM peak hour is typically evaluated, as it is generally when peak traffic volumes occur on the roadways. Three analysis periods were considered for winter – Friday, Saturday, and Sunday. The Friday PM peak hour is expected to have the biggest change in operations compared to existing conditions and was therefore studied. A more detailed explanation of the selection process for the winter analysis period is provided in the Winter Trip Generation section of this memo.

Summer

The existing HMR does not have any regular summer uses on site. The Lake Tahoe Music Festival holds one or two concerts per summer at Homewood. Since the event only occurs twice a summer, at most, it was not included when analyzing the existing summer trip generation of the site.

Winter

Existing winter traffic volumes generated by HMR were developed using traffic counts and parking data collected by the applicant. The existing winter trip generation (shown in **Table 1**) was developed based on the following steps:

1.) Counts were collected by a consultant hired by the applicant at all of the driveways and access roads to HMR during the AM and PM peak periods on Saturday, December 30, 2006. The PM peak hour volumes at the driveways are shown in the table, as well as the total two-way volume during the count periods (8:15 – 10:00AM and 2:15-5:00PM).

2.) HMR collects daily peak parking data on a regular basis. This data shows that on the day the traffic counts were collected at the driveways, 789 parking spaces were occupied. Parking data collected during the 2007-2008 and 2008-2009 ski seasons (including holidays) was reviewed to determine the peak Friday attendance at the existing site. The five highest Fridays of parking space occupancy for each of the 2007-2008 and 2008-2009 ski seasons were averaged. The results show that on a typical peak Friday, approximately 532 parking spaces are occupied.

3.) The ratio of average peak Friday parking space occupancy over occupied parking spaces on the day of the traffic counts (532 / 789 = 0.67) was used to factor the two-way volume during the count period, and estimate PM peak hour traffic volumes on a peak Friday.

4.) Data collected at Heavenly Ski Resort in Lake Tahoe provided the hourly variation of ski area traffic over the course of a day. This information was used to determine the total daily traffic volumes based on the peak period volumes collected at HMR.

5.) Fawn Drive and Tahoe Ski Bowl Way provide access for residential units (permanently occupied and recreational homes), as well as the ski resort. Trip generation estimates were calculated (using ITE *Trip Generation, Eighth Edition*) for the units and subtracted from the ski area trip generation estimates.

TABLE 1
EXISTING WINTER FRIDAY TRIP GENERATION SUMMARY

	Calculation Factors	Daily Trips	PM Peak Hour Trips	
			In	Out
Traffic Volumes Counted at Driveways (Saturday - 12/30/06)			194	550
Total Two-Way Volume in Count Periods (8:15-10:00 AM, 2:15-5:00 PM)	2,347			
Ski Area Parking Count on Date of Count	789			
Average Peak Friday Parking for 2007-2008 and 2008-2009 Ski Seasons	532			
Ratio of Friday Parking vs. Parking on Date of Count	0.67			
Estimated Traffic Volume on Peak Friday	1,572		130	369
Ratio of Total Daily Traffic to Traffic During Count Period	1.79			
Total Daily Traffic on Peak Friday		2,815		
Traffic Generated by Other Land Uses in Count Area		(-280)	(-15)	(-12)
Total Estimated Friday Traffic Generation of Existing Ski Area		2,535	115	357

Source: Fehr & Peers, 2009

The existing HMR generates 2,535 daily trips on the typical peak Friday, and 472 PM peak hour trips.

TYPICAL TRIP GENERATION RATES

Vehicle trips were generated for the HMR development using trip generation rates from *Trip Generation, Eighth Edition* (Institute of Transportation Engineers (ITE), 2008) and the TRPA Trip Table (Tahoe Regional Planning Agency, 2004).

A daily trip generation rate is not provided by TRPA or ITE for a Miniature Golf Course (summer only land use). It is a typical practice methodology to assume that the PM peak hour rate is 10% of the daily rate; therefore, this assumption was used to determine the daily trip generation rate for the Miniature Golf Course.

Standard trip generation rates are not available for a destination ski resort; therefore, the foundation for winter season trip generation calculations in this analysis is resort occupancy, maximum carrying capacity of the mountain, and the fluctuation or "turnover" of resort residents and guests.

Pass-By, Internal Capture, and Mode Split

Pass-by trips are made as intermediate stops on the way from an origin to a primary trip destination without a route diversion. For example, someone who regularly drives on SR 89 to go home from work stops at the retail use and then continues on their regular route would be considered a pass-by trip. No additional vehicle trips are added to the external roadway network.

In a mixed use development it is expected that trips will be made internally within the development. For example, people who live in the residential units on-site will travel to the retail or restaurant uses, and then return home. Their trip making activity never ventures to the external roadway network. By applying an internal capture reduction rate to the overall project trip generation, the number of estimated vehicle trips added to the surrounding roadway network is reduced.

Alternative modes of travel are also considered when analyzing project sites that are located near accessible bicycle and pedestrian paths and transit stops. Alternative mode reduction rates account for trips that are made by means other than a vehicle.

SUMMER TRIP GENERATION (ALTERNATIVE 1)

Assumed Accessory Uses

The ITE description of the hotel land use category includes accessory uses such as restaurants, cocktail lounges, meeting and banquet rooms or convention facilities, limited recreational facilities (pool, fitness room), and/or other retail and service shops. Based on this definition, the restaurant, bar, meeting space, and fitness center/spa uses were included as accessory uses to the hotel for analysis purposes.

Land Uses

The following land uses were included in the trip generation analysis of the proposed project (Alternative 1):

<u>North Base</u>

- Hotel - 75 rooms
  - Accessory uses include:
    - Meeting Space – 3,005 square feet
    - Fitness Center/Spa –10,590 square feet
    - Restaurant – 1,800 square feet
    - Bar – 1,260 square feet
- Condo/Hotel Rooms – 60 units (40 units, 20 with lock-offs)
- Penthouse Condos – 30 units

FEHR & PEERS
TRANSPORTATION CONSULTANTS

- Residential Condos – 36 units
- Fractional Condos (Timeshares) - 20 units
- Townhomes – 16 units
- Apartment (Workforce Housing) – 13 units
- Retail – 25,000 square feet (CFA)*
- Miniature Golf Course – 12 holes
- North Base Lodge/Skier Services – 30,000 square feet (winter only)
- Outdoor Amphitheater – 1,500 seats (special events only – infrequent use)

<u>South Base</u>

- Residential Condos – 99 units
- Skier Services – 2,000 square feet (winter only)

<u>Mid Mountain</u>

- Day Lodge – 15,000 square feet (winter only)

* Note: The applicant has indicated the 25,000 square feet of commercial floor area (CFA) at the North Base may be reduced or split between the North Base and Mid Mountain Day Lodge. Further analysis will incorporate any changes.

Analysis Methodology

Trip generation estimates for HMR were developed through comprehensive evaluation of the variety of land uses within the resort, the internal interaction of these uses, and the interaction between the project and the surrounding community.

The foundation for summer trip generation calculations in this analysis is resort occupancy and the fluctuation or "turnover" of resort residents and guests. This study takes a conservative approach and assumes that 100% of the lodging units are occupied on peak weekends. Monday and Thursday occupancy rates are estimated at 50% with mid-week occupancies around 35%.

The following steps were taken to develop summer trip generation estimates for the proposed project:

- Based on the information discussed above, it was assumed that 50% of the lodging guests will arrive at the resort on Friday. To present a conservative analysis, it was further assumed that all 50% of the lodging guests will arrive during the PM peak hour. It was also estimated that an average of 1.5 vehicles will arrive per lodging unit.
- Trips were generated for the remaining 50% of lodging units and the residential units using typical TRPA and ITE trip generation rates. Trips were also generated for the retail uses using these rates.
- The North Base Lodge, Mid Mountain Day Lodge, and other skier services buildings are generally winter-only uses. Any summer operation of these uses is expected to be 100% internalized. The purpose of these uses is to accommodate skiers (in the winter) and resort guests.

Internal Capture, Mode Split, and Pass-By Reductions

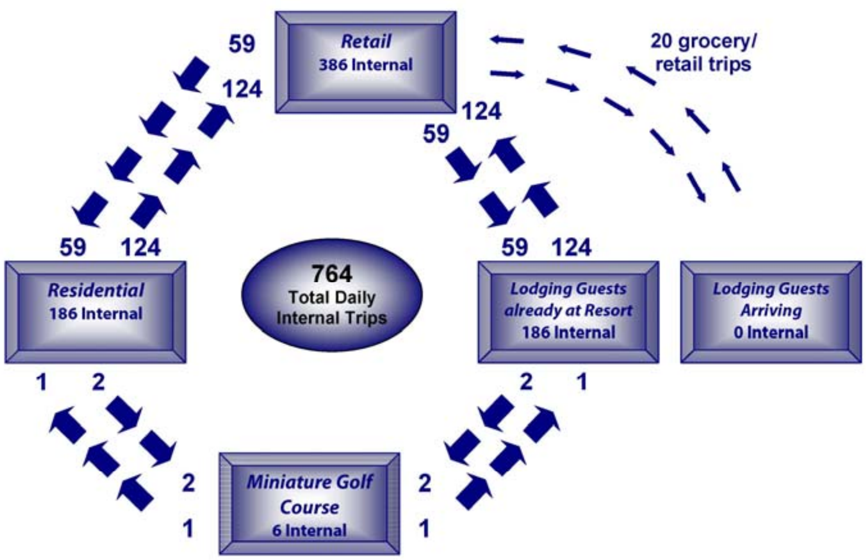
Internal Capture

The ITE *Trip Generation Handbook* provides procedures and data for estimating internal capture at mixed use project sites. The ITE information was used, however some of the defaults in the calculations spreadsheet were modified to reflect local information. U.S. Census data was utilized to determine the number of households in the vicinity of the project. Daily trips were estimated for the households and compared to the number of daily trips generated by the residential and hotel uses of the project. The comparison was used to modify the internal interaction between the residential and retail uses of the project.

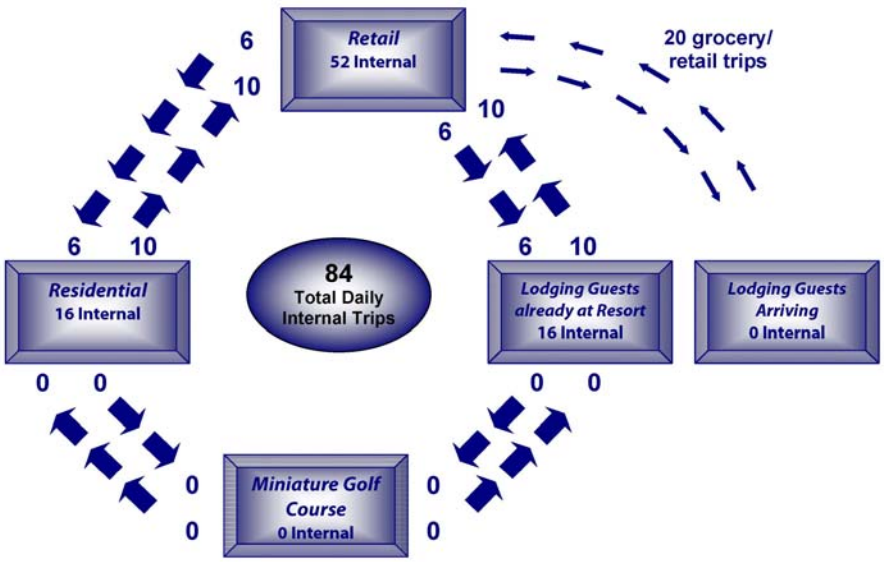
The internal trips between the retail, residential and lodging guests already at the resort were calculated using ITE methodology and are shown in the figures below. The internal trips between the retail and lodging guests arriving on Friday were also calculated, using ITE methodology, to account for guests who stop at the grocery store/retail to stock up on supplies during their stay at the resort upon their arrival. Therefore, the trips entering and exiting the retail as lodging guests arrive were counted as internal trips to the retail uses.

The figures below provide a visual representation of the internal interaction between the proposed project uses for the daily and PM peak hour analysis periods.

Daily



PM Peak



Alternative Modes of Travel

Fehr & Peers has completed considerable research to develop a series of trip generation equations that are used to evaluate the potential for alternative modes of travel to a development. The data used to develop the Fehr & Peers mixed use equations has been validated through comparison to field data and accounts for project land uses and sizes, population and employment created by the project, number of transit stops and intersections within the project site, employment within one mile of the project site, employment within a 30 minute transit trip, and the regional jobs to housing ratio.

The analysis estimates that 6% of trips generated by HMR will use alternative modes of travel.

Pass-By

The following pass-by rate, presented in *Trip Generation Handbook* (ITE, 2004), was used for the project:

- Shopping Center – 34%

Transit/Shuttle Service Provided by Homewood Mountain Resort

HMR is proposing to provide a shuttle service between Homewood and Tahoe City, and a Dial-A-Ride service, during the summer season. The HMR shuttle service will operate hourly from 7:00AM – 11:00PM. Trips generated at the HMR driveways by the shuttle service (32 daily trips, 2 PM peak hour trips) were added to the trip generation estimates.

A Dial-A-Ride service will be provided and will include up to 10 vans. It is estimated that 20 calls can be served during the peak hour (40 total PM peak hour trips) on a busy day. During off-peak hours, it is assumed that 10 calls will be served each hour (20 trips per hour), during a 16 hour service day. Assuming two peak hours during the day (80 peak hour trips), and 14 off-peak hours (280 trips), the daily trip generation of the Dial-A-Ride service is 360 daily trips.

FEHR & PEERS
TRANSPORTATION CONSULTANTS

Trip Generation Summary

Table 2 presents a summary of the trip generation for the proposed project including internal capture, mode splits, and pass-by reductions. Please see the attachments for the complete trip generation spreadsheet.

TABLE 2
PROPOSED PROJECT (ALTERNATIVE 1) SUMMER TRIP GENERATION SUMMARY

Land Use (ITE Code)	Density[1]	Rates[2]				Trips[3]			
		Daily	PM	PM In	PM Out	Daily	PM	PM In	PM Out
North Base									
*50% of lodging guests arrive on Friday **

Fitness Center/Spa	10.59 ksf	Accessory Use to Hotel							
Restaurant	1.80 ksf	Accessory Use to Hotel							
Bar	1.26 ksf	Accessory Use to Hotel							
Miniature Golf Course (431)	12 holes	3.30	0.33	33%	67%	40	4	1	3
South Base									
Residential Condos (230)	99 units	5.86	0.52	67%	33%	580	51	34	17
Total "Raw" Trip Generation						3,011	386	275	111
Internal Capture Trips						(-764)	(-84)	(-42)	(-42)
External Project Trips						*2,247*	*302*	*233*	*69*
Alternative Mode Trips [4] (6%)						(-135)	(-18)	(-14)	(-4)
External Vehicle Trips						*2,112*	*284*	*219*	*65*
Pass-By Trips [4] (Shopping Center – 34%)						(-220)	(-25)	(-12)	(-13)
HMR Shuttle Trips						32	2	1	1
Dial-A-Ride Trips						360	80	40	40
Total Net New External Roadway Trips						**2,284**	**341**	**248**	**93**

Notes: [1] ksf = 1,000 square feet

[2] Daily rates are from the TRPA Trip Table and PM rates are from ITE. ITE Daily rates were used where the TRPA Trip Table did not provide rates.

[3] Numbers may differ slightly from the trip generation spreadsheet due to rounding.

[4] Alternative Mode trips (6%) were subtracted from the external project trips. Pass-By trips were subtracted from the external vehicle trips.

The proposed project (Alternative 1) is expected to generate 2,284 net new daily trips and 341 Friday PM peak hour trips on the external roadway network during the summer season.

WINTER TRIP GENERATION (ALTERNATIVE 1)

Winter Study Period

Typically, traffic volumes in the Lake Tahoe Basin are highest during the summer months; therefore, traffic analysis is usually performed for the summer condition. However, the proposed project is a major winter trip generator due to the ski operation. Therefore, the winter trip generation was evaluated. Three winter study periods were considered for analysis of the proposed HMR – Friday, Saturday, and Sunday. Each study period was qualitatively evaluated to determine which period would result in the highest net new trip generation (accounting for the existing ski resort operation).

- Friday - The Friday PM peak hour is expected to have the biggest change in operations compared to existing conditions. Currently the resort is primarily occupied by day skiers who arrive in the morning and leave in the afternoon/evening. The proposed project will include skier accommodations, residential and lodging units, and retail uses. These uses will change the distribution of vehicle trips in to and out of the project site. Currently, the majority of vehicle trips exit the resort during the PM peak hour; however, with the proposed project, the day skiers will still leave at the end of the day, but a large portion of the lodging guests will arrive during the Friday PM peak hour.
- Saturday - The proposed project is expected to generate fewer trips than the existing HMR on Saturday. The skier capacity of the mountain is not expected to change, and the number of day skier parking spaces will be reduced by approximately 70%. The remaining skier capacity of the mountain is expected to be filled with the residents and hotel guests. Since the residents already live at the project site, they will not be generating new trips to the resort, and the majority of hotel guests will likely arrive and leave, prior to and after, Saturday.
- Sunday – As mentioned, the skier capacity of the mountain will not change, just the mix of attendees. Currently, a majority of the skiers are day skiers who leave the resort at the end of the day. With the proposed project, the smaller number of day skiers will still be leaving during the Sunday peak hour, as well as the people who are lodging at the site. The trip generation on a winter Sunday will be similar for the proposed project and the existing facility; therefore, the proposed project will not result in new trips to the roadway network.

Based on this qualitative assessment, we propose to analyze winter Friday PM peak hour conditions.

Assumed Accessory Uses

The ITE description of the hotel land use category includes accessory uses such as restaurants, cocktail lounges, meeting and banquet rooms or convention facilities, limited recreational facilities (pool, fitness room), and/or other retail and service shops; therefore, the restaurant, bar, meeting space, and fitness center/spa uses were included as accessory uses to the hotel for analysis purposes.

Land Uses

The following land uses were included as part of the proposed project (Alternative 1):

<u>North Base</u>

- Hotel - 75 rooms
  - Accessory uses include: Meeting Space – 3,005 square feet
    Fitness Center/Spa –10,590 square feet
    Restaurant – 1,800 square feet
    Bar – 1,260 square feet
- Condo/Hotel Rooms – 60 units (40 units, 20 with lock-offs)
- Penthouse Condos – 30 units
- Residential Condos – 36 units
- Fractional Condos (Timeshares) - 20 units
- Townhomes – 16 units
- Apartment (Workforce Housing) – 13 units
- Retail – 25,000 square feet
- Miniature Golf Course – 12 holes (summer only)
- North Base Lodge/Skier Services – 30,000 square feet
- Outdoor Amphitheater – 1,500 seats (summer only)
- Day Skier Parking – 270 spaces

<u>South Base</u>

- Residential Condos – 99 units
- Skier Services – 2,000 square feet

<u>Mid Mountain</u>

- Day Lodge – 15,000 square feet

Analysis Methodology

Winter trip generation estimates for HMR were developed through comprehensive evaluation of the variety of land uses within the resort, the internal interaction of these uses, and the interaction between the project and the surrounding community. Standard trip generation rates are not available for a destination ski resort, therefore land use specific trip analysis, considering internal trip making, is necessary for the proposed project.

The foundation for trip generation calculations in this analysis is resort occupancy, maximum carrying capacity of the mountain, and the fluctuation or “turnover” of resort residents and guests. This study takes a conservative approach and assumes that 100% of the lodging units are occupied on peak weekends. Monday and Thursday occupancy rates are estimated at 50% with mid-week occupancies around 35%. Based on data collected by the Park City Chamber of Commerce, the length of a typical stay at a ski resort is 3 to 5 days, with most arrivals on Fridays and the majority of departures on Sundays.

The maximum carrying capacity of the mountain is not going to change, however the number of day skier parking spaces will be reduced to 270 (approximately 70% of existing). This indicates that the majority of skiers at the proposed project site will also be lodging at the resort, or residents on the property.

The following steps were taken to develop winter trip generation estimates for the proposed project:

- Friday parking data collected by HMR during the 2007-2008 and 2008-2009 ski seasons (including holidays) was reviewed to determine the peak Friday attendance at the existing site. The five highest Fridays of parking space occupancy for each of the 2007-2008 and 2008-2009 ski seasons were averaged. The results showed that on a typical peak Friday, the day skier parking spaces are approximately 56% occupied. This factor was applied to the 270 proposed day skier parking spaces to determine the number of occupied spaces on a peak Friday at the proposed project (270 x 56% = 151 occupied spaces). It was assumed that all occupied spaces will be vacated during the PM peak hour for analysis purposes. Daily trip generation was determined by doubling the number of occupied spaces (to account for the entering trip and exiting trip made by each vehicle).
- Based on the information discussed previously, it was assumed that 50% of the lodging guests will arrive at the resort on Friday. To present a conservative analysis, it was further assumed that all 50% of the lodging guests will arrive during the PM peak hour. It was also estimated that an average of 1.5 vehicles will arrive per lodging unit.
- Trips were generated for the remaining 50% of lodging units and the residential units using typical TRPA and ITE trip generation rates. Trips were also generated for the retail uses using these rates.
- Trips generated by the North Base Lodge, Mid Mountain Day Lodge, and other skier services buildings are expected to be 100% internalized. The purpose of these uses is to accommodate skiers and resort guests.
- The same methodology used for summer trip generation was used to determine the internal capture, alternative mode, and pass-by reductions for the winter analysis.

Internal Capture, Mode Split, and Pass-By Reductions

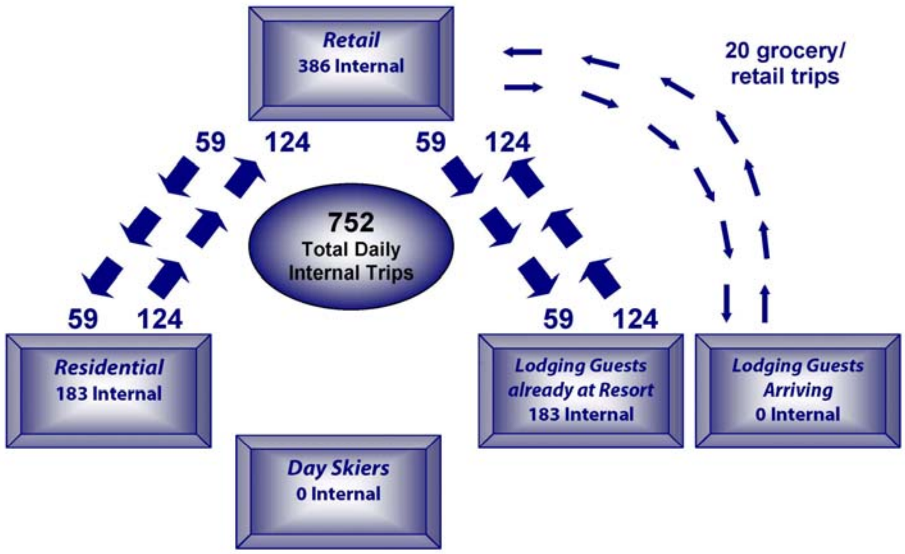
<u>Internal Capture</u>

The internal trips between the retail, residential and lodging guests already at the resort were calculated using ITE methodology and are shown in the figures below. The internal trips between the retail and lodging guests arriving on Friday were also calculated, using ITE methodology, to account for guests who stop at the grocery store/retail to stock up on supplies during their stay at the resort upon their arrival. Therefore, the trips entering and exiting the retail, as lodging guests arrive, were counted as internal trips to the retail uses.

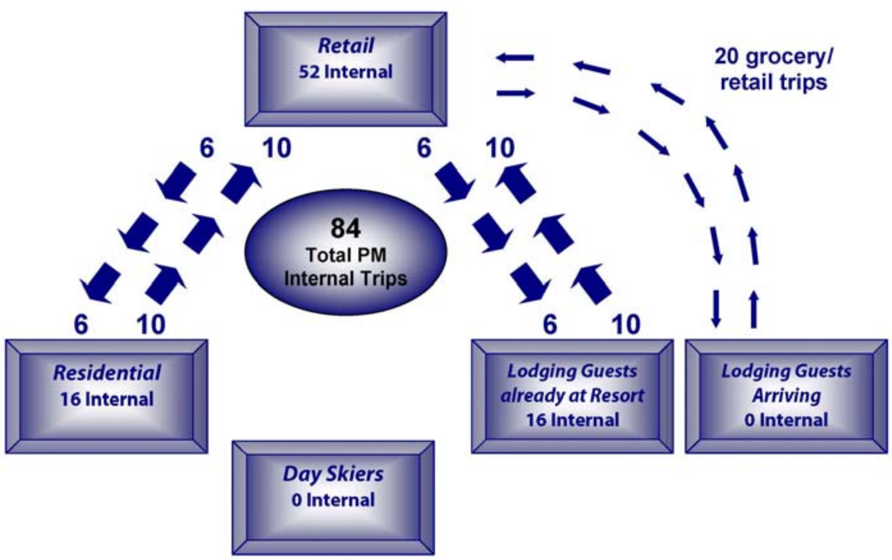
Note that the estimate of internal trips is conservative because no internal capture was applied to the day skiers, and they will likely go to the retail uses.

The figures below provide a visual representation of the internal interaction between the proposed project uses for the daily and PM peak hour analysis periods.

Daily



PM Peak



Alternative Modes of Travel

The Fehr & Peers mixed use equations were used to determine the alternative mode reduction rate of the project. The analysis estimates that 6% of trips generated by HMR will use alternative modes of travel.

Pass-By

The following pass-by rate, presented in *Trip Generation Handbook* (ITE, 2004), was used for the project:

- Shopping Center – 34%

Transit/Shuttle Service Provided by Homewood Mountain Resort and Skier Drop Off and Pick Up

Transit/Shuttle Service

HMR is proposing to provide skier shuttles to and from HMR. Each shuttle will have a 12 skier capacity, but to provide a conservative analysis, it is assumed that each shuttle is only half full. It is assumed that 100 skiers will use the shuttle daily. During the PM peak hour it is estimated that 17 buses (to accommodate all 100 skiers) will enter and exit HMR. The total daily trip generation of the skier shuttles is 68 trips.

A Dial-A-Ride service will be provided and will include up to 10 vans. It is estimated that 20 calls can be served during the peak hour (40 total PM peak hour trips) on a busy day. During off-peak hours, it is assumed that 10 calls will be served each hour (20 trip per hour), during a 16 hour service day. Assuming two peak hours during the day (80 peak hour trips), and 14 off-peak hours (280 trips), the daily trip generation of the Dial-A-Ride service is 360 daily trips.

Skier Drop Off and Pick Up

For analysis purposes it was assumed that 100 day use skiers will be dropped off and picked up from HMR. Assuming a vehicle occupancy of 2.5 skiers per vehicle, drop off/pick up trips will account for 80 PM peak hour trips and 160 daily trips.

Trip Generation Summary

Table 3 presents a summary of the trip generation for the proposed project including internal capture, mode splits, and pass-by reductions. Please see the attachments for the complete trip generation spreadsheet.

Bar	1.26 ksf	Accessory Use to Hotel							
South Base									
Residential Condos (230)	99 units	5.86	0.52	67%	33%	580	51	34	17
Total "Raw" Trip Generation						3,275	534	274	260
Internal Capture Trips						(-752)	(-84)	(-42)	(-42)
External Project Trips						*2,523*	*450*	*232*	*218*
Alternative Mode Trips [4] (6%)						(-151)	(-27)	(-14)	(-13)
External Vehicle Trips						*2,372*	*423*	*218*	*205*
Pass-By Trips [4] (Shopping Center – 34%)						(-220)	(-13)	(-6)	(-7)
Skier Drop Off and Pick Up						160	40	20	20
HMR Shuttle Service						68	34	17	17
Dial-A-Ride						360	80	40	40
Total New Project Trips						**2,740**	**564**	**289**	**275**
Existing Homewood Volumes						(-2,535)	(-472)	(-115)	(-357)
Total Net New External Roadway Trips						**205**	**92**	**174**	**(-82)**

Notes: * An average of 1.5 vehicles per unit was assumed.
[1] ksf = 1,000 square feet
[2] Daily rates are from the TRPA Trip Table and PM rates are from ITE. ITE Daily rates were used where the TRPA Trip Table did not provide rates.
[3] Numbers may differ slightly from the trip generation spreadsheet due to rounding.
[4] Alternative Mode trips (6%) were subtracted from the external project trips. Pass-By trips were subtracted from the external vehicle trips.

The proposed project (Alternative 1) is expected to generate 205 net new daily trips, and 92 net new Friday PM peak hour trips on the external roadway network during the winter season.

However, the directional split of trips during the Friday PM peak hour will change. The number of trips entering HMR will increase by 174, and the number exiting trips will decrease by 82 compared to existing conditions.

TRIP DISTRIBUTION

Vehicle trips generated by the project were distributed to the roadway network based on travel patterns in the study area and locations of complementary land uses. The trip distribution and assignment for the proposed project is described below:

- 11% enter/exit from/to the south on SR 89
- 89% enter/exit from/to the north on SR 89
    - 45% enter/exit from/to the west on SR 89
    - 55% enter/exit from/to the east on SR 28
- Vehicle trips entering and exiting the driveway access points of the project site were distributed based on the locations of the land uses and parking facilities on site.

Technical Advisory

CEQA AND CLIMATE CHANGE: Addressing Climate Change Through California Environmental Quality Act (CEQA) Review

This technical advisory is one in a series of advisories provided by the Governor's Office of Planning and Research (OPR) as a service to professional planners, land use officials and CEQA practitioners. OPR issues technical guidance from time to time on issues that broadly affect the practice of CEQA and land use planning. The emerging role of CEQA in addressing climate change and greenhouse gas emissions has been the topic of much discussion and debate in recent months. This document provides OPR's perspective on the issue.

I. PURPOSE

General scientific consensus and increasing public awareness regarding global warming and climate change have placed new focus on the California Environmental Quality Act (CEQA) review process as a means to address the effects of greenhouse gas (GHG) emissions from proposed projects on climate change. Many public agencies—along with academic, business, and community organizations—are striving to determine the appropriate means by which to evaluate and mitigate the impacts of proposed projects on climate change. Approaches and methodologies for calculating GHG emissions and addressing the environmental impacts through CEQA review are rapidly evolving and are increasingly available to assist public agencies to prepare their CEQA documents and make informed decisions.

JUNE 19, 2008

STATE OF CALIFORNIA

www.opr.ca.gov

The Governor's Office of Planning and Research (OPR) will develop, and the California Resources Agency (Resources Agency) will certify and adopt amendments to the Guidelines implementing the California Environmental Quality Act ("CEQA Guidelines"), on or before January 1, 2010, pursuant to Senate Bill 97 (Dutton, 2007). These new CEQA Guidelines will provide regulatory guidance on the analysis and mitigation of GHG emissions in CEQA documents. In the interim, OPR offers the following informal guidance regarding the steps lead agencies should take to address climate change in their CEQA documents. This guidance was developed in cooperation with the Resources Agency, the California Environmental Protection Agency (Cal/EPA), and the California Air Resources Board (ARB).

II. BACKGROUND

Climate change refers to any significant change in measures of climate, such as average temperature, precipitation, or wind patterns over a period of time. Climate change may result from natural factors, natural processes, and human activities that change the composition of the atmosphere and alter the surface and features of the land. Significant changes in global climate patterns have recently been associated with global warming, an average increase in the temperature of the atmosphere near the Earth's surface, attributed to accumulation of GHG emissions in the atmosphere. Greenhouse gases trap heat in the atmosphere, which in turn heats the surface of the Earth. Some GHGs occur naturally and are emitted to the atmosphere through natural processes, while others are created and emitted solely through human activities. The emission of GHGs through the combustion of fossil fuels (i.e., fuels containing carbon) in conjunction with other human activities, appears to be closely associated with global warming.

State law defines GHG to include the following: carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), hydrofluorocarbons, perfluorocarbons, and sulfur hexafluoride (Health and Safety Code, section 38505(g).) The most common GHG that results from human activity is carbon dioxide, followed by methane and nitrous oxide.

Requirements of AB 32 and SB 97

Assembly Bill 32 (AB 32), the California Global Warming Solutions Act of 2006 (Nunez, 2006), recognizes that California is the source of substantial amounts of GHG emissions. The statute begins with several legislative findings and declarations of intent, including the following:

> Global warming poses a serious threat to the economic well-being, public health, natural resources, and the environment of California. The potential adverse impacts of global warming include the exacerbation of air quality problems, a reduction in the quality and supply of water to the state from the Sierra snow pack, a rise in sea levels resulting in the displacement of thousands of coastal businesses and residences, damage to marine ecosystems and the natural environment, and an increase in the incidences of infectious diseases, asthma, and other human health-related problems. (Health and Safety Code, section 38501.)

In order to avert these consequences, AB 32 establishes a state goal of reducing GHG emissions to 1990 levels by the year 2020 (a reduction of approximately 25 percent from forecast emission levels) with further reductions to follow. The law requires the ARB to establish a program to track and report GHG emissions; approve a scoping plan for achieving the maximum technologically feasible and cost effective reductions from sources of GHG emissions; adopt early reduction measures to begin moving forward; and adopt, implement and enforce regulations – including market mechanisms such as "cap-and-trade" programs – to ensure the required reductions occur. The ARB recently adopted a statewide GHG emissions limit and an emissions inventory, along with requirements to measure, track, and report GHG emissions by the industries it determined to be significant sources of GHG emissions.

CEQA requires public agencies to identify the potentially significant effects on the environment of projects they intend to carry out or approve, and to mitigate significant effects whenever it is feasible to do so. While AB 32 did not amend CEQA to require new analytic processes to account for the environmental impacts of GHG emissions from projects subject to CEQA, it does acknowledge that such emissions cause significant adverse impacts to human health and the environment.

Senate Bill 97, enacted in 2007, amends the CEQA statute to clearly establish that GHG emissions and the effects of GHG emissions are appropriate subjects for CEQA analysis. It directs OPR to develop draft CEQA Guidelines "for the mitigation of greenhouse gas emissions or the effects of greenhouse gas emissions" by July 1, 2009 and directs the Resources Agency to certify and adopt the CEQA Guidelines by January 1, 2010.

Requirements of CEQA

CEQA is a public disclosure law that requires public agencies to make a good-faith, reasoned effort, based upon available information, to identify the potentially significant direct and indirect environmental impacts—including cumulative impacts— of a proposed project or activity. The CEQA process is intended to inform the public of the potential environmental effects of proposed government decisions and to encourage informed decision-making by public agencies. In addition, CEQA obligates public agencies to consider less environmentally-damaging alternatives and adopt feasible mitigation measures to reduce or avoid a project's significant impacts.

The lead agency is required to prepare an Environmental Impact Report (EIR), a Mitigated Negative Declaration, or equivalent document, when it determines that the project's impacts on the environment are potentially significant. This determination of significance must be based upon substantial evidence in light of all the information before the agency.

Although the CEQA Guidelines, at Appendix G, provide a checklist of suggested issues that should be addressed in an EIR, neither the CEQA statute nor the CEQA Guidelines prescribe thresholds of significance or particular methodologies for performing an impact analysis. This is left to lead agency judgment and discretion, based upon factual data and guidance from regulatory agencies and other sources where available and applicable. A threshold of significance is essentially a regulatory standard or set of criteria that represent the level at which a lead agency finds a particular environmental effect of a project to be significant. Compliance with a given threshold means the effect normally will be considered less than significant. Public agencies are encouraged but not required to adopt thresholds of significance for environmental impacts. Even in the absence of clearly defined thresholds for GHG emissions, the law requires that such emissions from CEQA projects must be disclosed and mitigated to the extent feasible whenever the lead agency determines that the project contributes to a significant, cumulative climate change impact.

We realize that perhaps the most difficult part of the climate change analysis will be the determination of significance. Although lead agencies typically rely on local or regional definitions of significance for most environmental issues, the global nature of climate change warrants investigation of a statewide threshold of significance for GHG emissions. To this end, OPR has asked ARB technical staff to recommend a method for setting thresholds which will encourage consistency and uniformity in the CEQA analysis of GHG emissions throughout the state. Until such time as state guidance is available on thresholds of significance for GHG emissions, we recommend the following approach to your CEQA analysis.

III. RECOMMENDED APPROACH

Each public agency that is a lead agency for complying with CEQA needs to develop its own approach to performing a climate change analysis for projects that generate GHG emissions. A consistent approach should be applied for the analysis of all such projects, and the analysis must be based on best available information. For these projects, compliance with CEQA entails three basic steps: identify and quantify the GHG emissions; assess the significance of the impact on climate change; and if the impact is found to be significant, identify alternatives and/or mitigation measures that will reduce the impact below significance.

Lead agencies should determine whether greenhouse gases may be generated by a proposed project, and if so, quantify or estimate the GHG emissions by type and source. Second, the lead agency must assess whether those emissions are individually or cumulatively significant. When assessing whether a project's effects on climate change are "cumulatively considerable" even though its GHG contribution may be individually limited, the lead agency must consider the impact of the project when viewed in connection with the effects of past, current, and probable future projects. Finally, if the lead agency determines that the GHG emissions from the project as proposed are potentially significant, it must investigate and implement ways to avoid, reduce, or otherwise mitigate the impacts of those emissions. Although the scientific knowledge and understanding of how best to perform this analysis is rudimentary and still evolving, many useful resources are available (see Attachment 1).

Until such time as further state guidance is available on thresholds of significance, public agencies should consider the following general factors when analyzing whether a proposed project has the potential to cause a significant climate change impact on the environment.

Identify GHG Emissions

- Lead agencies should make a good-faith effort, based on available information, to calculate, model, or estimate the amount of CO_2 and other GHG emissions from a project, including the emissions associated with vehicular traffic, energy consumption, water usage and construction activities.
- Technical resources, including a variety of modeling tools, are available to assist public agencies to quantify GHG emissions. OPR recognizes that more sophisticated emissions models for particular types of projects are continually being developed and that the state-of-the-art quantification

models are rapidly changing. OPR will periodically update the examples of modeling tools identified in Attachment 2.

- There is no standard format for including the analysis in a CEQA document. A GHG/climate change analysis can be included in one or more of the typical sections of an EIR (e.g., air quality, transportation, energy) or may be provided in a separate section on cumulative impacts or climate change.

Determine Significance

- When assessing a project's GHG emissions, lead agencies must describe the existing environmental conditions or setting, without the project, which normally constitutes the baseline physical conditions for determining whether a project's impacts are significant.
- As with any environmental impact, lead agencies must determine what constitutes a significant impact. In the absence of regulatory standards for GHG emissions or other scientific data to clearly define what constitutes a "significant impact", individual lead agencies may undertake a project-by-project analysis, consistent with available guidance and current CEQA practice.
- The potential effects of a project may be individually limited but cumulatively considerable. Lead agencies should not dismiss a proposed project's direct and/or indirect climate change impacts without careful consideration, supported by substantial evidence. Documentation of available information and analysis should be provided for any project that may significantly contribute new GHG emissions, either individually or cumulatively, directly or indirectly (e.g., transportation impacts).
- Although climate change is ultimately a cumulative impact, not every individual project that emits GHGs must necessarily be found to contribute to a significant cumulative impact on the environment. CEQA authorizes reliance on previously approved plans and mitigation programs that have adequately analyzed and mitigated GHG emissions to a less than significant level as a means to avoid or substantially reduce the cumulative impact of a project.

Mitigate Impacts

- Mitigation measures will vary with the type of project being contemplated, but may include alternative project designs or locations that conserve energy and water, measures that reduce vehicle miles traveled

(VMT) by fossil-fueled vehicles, measures that contribute to established regional or programmatic mitigation strategies, and measures that sequester carbon to offset the emissions from the project.

- The lead agency must impose all mitigation measures that are necessary to reduce GHG emissions to a less than significant level. CEQA does not require mitigation measures that are infeasible for specific legal, economic, technological, or other reasons. A lead agency is not responsible for wholly eliminating all GHG emissions from a project; the CEQA standard is to mitigate to a level that is "less than significant".
- If there are not sufficient mitigation measures that the lead agency determines are feasible to achieve the less than significant level, the lead agency should adopt those measures that are feasible, and adopt a Statement of Overriding Considerations that explains why further mitigation is not feasible. A Statement of Overriding Considerations must be prepared when the lead agency has determined to approve a project for which certain impacts are unavoidable. These statements should explain the reasons why the impacts cannot be adequately mitigated in sufficient detail, and must be based on specific facts, so as not to be conclusory.
- Agencies are encouraged to develop standard GHG emission reduction or mitigation measures that can be applied on a project-by-project basis. Attachment 3 contains a preliminary menu of measures that lead agencies may wish to consider. This list is by no means exhaustive or prescriptive. Lead agencies are encouraged to develop their own measures and/or propose project alternatives to reduce GHG emissions, either at a programmatic level or on a case-by-case review.
- In some cases GHG emission reduction measures will not be feasible or may not be effective at a project level. Rather, it may be more appropriate and more effective to develop and adopt program-level plans, policies and measures that will result in a reduction of GHG emissions on a regional level.

IV. ADDITIONAL LAND USE CONSIDERATIONS

CEQA can be a more effective tool for GHG emissions analysis and mitigation if it is supported and supplemented by sound development policies and practices that will reduce GHG emissions on a broad planning scale and that can provide the basis for a programmatic approach to project-specific CEQA analysis and mitigation.

Local governments with land use authority are beginning to establish policies that result in land use patterns and practices that will result in less energy use and reduce GHG emissions. For example, some cities and counties have adopted general plans and policies that encourage the development of compact, mixed-use, transit-oriented development that reduces VMT; encourage alternative fuel vehicle use; conserve energy and water usage; and promote carbon sequestration. Models of such developments exist throughout the state (see OPR climate change website for examples of city and county plans and policies, referenced in Attachment 1).

For local government lead agencies, adoption of general plan policies and certification of general plan EIRs that analyze broad jurisdiction-wide impacts of GHG emissions can be part of an effective strategy for addressing cumulative impacts and for streamlining later project-specific CEQA reviews.

International, national, and statewide organizations such as ICLEI (Local Governments for Sustainability), the Cities for Climate Protection, and the Clean Cities Coalition —to name just a few — have published guidebooks to help local governments reduce GHG emissions through land use planning techniques and improved municipal operations. Links to these resources are provided at the end of this advisory.

Regional agencies can also employ a variety of strategies to reduce GHG emissions through their planning processes. For example, regional transportation planning agencies adopt plans and programs that address congestion relief, jobs-to-housing balance, reduction of vehicle miles traveled (VMT), and other issues that have implications for GHG emission reductions.

State agencies are also tackling the issue of climate change. Some have adopted or support policies and programs that take climate change into account, including the Department of Water Resources' State Water Plan; the Department of Transportation's State Transportation Plan; and the Business, Housing and Transportation Agency's Regional Blueprint Planning Program. These efforts not only raise public awareness of climate change and how the State can reduce GHG emissions, but also offer specific information and resources for lead agencies to consider.

V. NEXT STEPS

OPR has asked ARB technical staff to recommend a method for setting a threshold of significance for GHG emissions. OPR has requested that the ARB identify a range of feasible options, including qualitative and quantitative options.

OPR is actively seeking input from the public and stakeholder groups, as it develops draft CEQA Guidelines for GHG emissions. OPR is engaged with the Resources Agency and other expert state agencies, local governments, builders and developers, environmental organizations, and others with expertise or an interest in the development of the Guidelines.

OPR will conduct public workshops later this year to receive input on the scope and content of the CEQA Guidelines amendments. It is OPR's intent to release a preliminary draft of the CEQA Guidelines amendments for public review and comment in the fall. This will enable OPR to deliver a proposed package of CEQA Guidelines amendments to the Resources Agency as early as January 2009, well before the statutory due date of July 1, 2009.

We encourage public agencies and the public to refer to the OPR website at www.opr.ca.gov for information about the CEQA Guidelines development process and to subscribe to OPR's notification system for announcements and updates.

Technical Resources/Modeling Tools to Estimate GHG Emissions

TOOL	AVAILABILITY	SCOPE LOCAL/ REGIONAL	SCOPE TRANSPORTATION/ BUILDINGS	DATA INPUT REQUIREMENTS	DATA OUTPUT
URBEMIS	• Download • Public domain (free)	• Local project level	• Transportation • Some building (area source) outputs • Construction	• Land use information • Construction, area source, and transportation assumptions	• CO2 (pounds per day) • Mitigation impacts
Clean Air and Climate Protection (CACP) Software	• Download • Available to public agencies (free)	• Local project level	• Buildings • Communities • Governments	• Energy usage • Waste generation and disposal • Transportation fuel usage or VMT	• CO2e (tons per year)
Sustainable Communities Model (SCM)	• Custom model	• Regional • Scalable to site level	• Transportation • Buildings • Neighborhoods • Master planned communities	• Location and site specific information • Transportation assumptions • On-site energy usage	• CO2e (tons per year)
Internet-accessed Planning for Community Energy, Economic and Environmental Sustainability I-PLACE^{3}S	• Web-based • Small access fee • Full model now available in eight CA counties	• Regional • Scalable to site level	• Transportation • Housing • Land Use • Buildings • Energy • Economics	• Parcel level land use data (ability to work with less data) • Project-level data for alternative comparisons	• CO2 (any quantity over any time)

Climate Action Registry Reporting On-Line Tool (CARROT)	• Web-based
	• Available to Registry members
	• General public can view entity reports
		• Regional, scalable to entity and facility level	• General Reporting and Certification Protocols
			  o Transportation
			  o Buildings/facilities
			• Specific protocols for some sectors
				• Mobile source combustion (VMT or fuel usage)
				• Stationary combustion (fuel usage)
				• Indirect emissions (electricity usage)
					• Each GHG and CO2e (tons per year)

EMFAC	• Download • Public domain (free)	• Statewide • Regional (air basin level)	• Transportation emission factors	• Travel activity data to calculate CO2 from projects.	• CO2 and methane (grams per mile) emission factors

VMT = Vehicle miles traveled
eCO2 = Carbon dioxide equivalent emissions
Note: This is not meant to be a definitive list of modeling tools to estimate climate change emissions impacts. Other tools may be available.

Description of Modeling Tools

URBEMIS

The Urban Emissions Model is used extensively during the CEQA process by local air districts and consultants to determine the impacts of projects on criteria pollutants. It was recently updated to calculate CO2 emissions as well. Future updates will include additional greenhouse gases. URBEMIS uses the ITE Trip Generation Rate Manual and the Air Resources Board's (ARB) motor vehicle emissions model (EMFAC) to calculate transportation-related CO2 emissions and ARB's OFFROAD2007 model for CO2 emissions from off-road equipment. Area source outputs include natural gas use, landscaping equipment, consumer products, architectural coatings, and fireplaces. It also estimates construction impacts and impacts of mitigation options. Web site: http://www.urbemis.com.

Clean Air and Climate Protection (CACP) Software

This tool is available to state and local governments and members of ICLEI, NACAA, NASEO and NARUC to determine greenhouse gas and criteria pollutant emissions from government operations and communities as a whole. The user must input aggregate information about energy (usage), waste (quantity and type generated, disposal method, and methane recovery rate) and transportation (VMT) for community analyses. CACP uses emission factors from EPA, DOE, and DOT to translate the energy, waste and transportation inputs into greenhouse gas (in carbon dioxide equivalents) and criteria air pollutant emissions. If associated energy, waste and transportation reduction are provided, the model can also calculate emission reductions and money saved from policy alternatives. Web site: http://cacpsoftware.org.

Sustainable Communities Model (SCM)

This model quantifies total CO2e emissions allowing communities the ability to optimize planning decisions that result in the greatest environmental benefit for the least cost. Total CO2e emissions are based on emissions from energy usage, water consumption and transportation. The model provides an interactive comparison of various scenarios to provide environmental performance, economic performance, and cost benefit analysis.

Web site: www.ctg-net.com/energetics/documents/doc_SCM_070731.pdf

I-PLACE^{3}S

This model is an internet-accessed land use and transportation model designed specifically for regional and local governments to help understand how their growth and development decisions can contribute to improved sustainability. It estimates CO2, criteria pollutant and energy impacts on a neighborhood or regional level for existing, long-term baseline and alternative land use plans. The data input requirements are extensive and require a fiscal commitment from the Metropolitan Planning Organization and its member local governments. Once the data is available, the IPLACES tool can be developed for that region relatively quickly, in approximately one week. The benefits include a multifunctional tool that provides immediate outputs to compare alternatives during public meetings, multilevel password protected on-line access, as well as providing access for local development project CEQA analyses. This tool also supports regional travel models and integrated land use and transportation assessments. Web site: http://www.sacregionblueprint.org/sacregionblueprint/the_project/technology.cfm and http://www.places.energy.ca.gov/places

CARROT

The California Climate Action Registry offers the Climate Action Registry Reporting On-Line Tool (CARROT) for Registry members to calculate and report annual greenhouse gas (GHG) emissions. CARROT calculates direct and indirect GHG emissions for the following emission categories by source: stationary combustion, process emissions, mobile source combustion, fugitive emissions and electricity use by source. It calculates emissions using entity collected data such as fuel purchase records, VMT and utility bills. While reporting and certification through CARROT is only available to members, the public may access entity reports online. Reporting protocols are also available to the public, including the General Reporting Protocol (www.climateregistry.org/docs/PROTOCOLS/GRP%20V2-March2007_web.pdf) and cement, forestry and power/utility sector protocols. Additional sector protocols are under development. Website: www.climateregistry.org/CARROT/

EMFAC

The Air Resources Board's EMission FACtors (EMFAC) model is used to calculate emission rates from all motor vehicles in California. The emission factors are combined with data on vehicle activity (miles traveled and average speeds) to assess emission impacts. The URBEMIS model described above uses EMFAC to calculate the transportation emission impacts of local projects. Web site: http://www.arb.ca.gov/msei/onroad/onroad.htm

Attachment 3

Examples of GHG Reduction Measures

The following are examples of measures that have been employed by some public agencies to reduce greenhouse gas emissions, either as general development policies or on a project-by-project basis. These are provided for illustrative purposes only.

LAND USE AND TRANSPORTATION

- Implement land use strategies to encourage jobs/housing proximity, promote transit-oriented development, and encourage high density development along transit corridors. Encourage compact, mixed-use projects, forming urban villages designed to maximize affordable housing and encourage walking, bicycling and the use of public transit systems.
- Encourage infill, redevelopment, and higher density development, whether in incorporated or unincorporated settings
- Encourage new developments to integrate housing, civic and retail amenities (jobs, schools, parks, shopping opportunities) to help reduce VMT resulting from discretionary automobile trips.
- Apply advanced technology systems and management strategies to improve operational efficiency of transportation systems and movement of people, goods and services.
- Incorporate features into project design that would accommodate the supply of frequent, reliable and convenient public transit.
- Implement street improvements that are designed to relieve pressure on a region's most congested roadways and intersections.
- Limit idling time for commercial vehicles, including delivery and construction vehicles.

URBAN FORESTRY

- Plant trees and vegetation near structures to shade buildings and reduce energy requirements for heating/cooling.
- Preserve or replace onsite trees (that are removed due to development) as a means of providing carbon storage.

GREEN BUILDINGS

- Encourage public and private construction of LEED (Leadership in Energy and Environmental Design) certified (or equivalent) buildings.

ENERGY CONSERVATION POLICIES AND ACTIONS

- Recognize and promote energy saving measures beyond Title 24 requirements for residential and commercial projects
- Where feasible, include in new buildings facilities to support the use of low/zero carbon fueled vehicles, such as the charging of electric vehicles from green electricity sources.
- Educate the public, schools, other jurisdictions, professional associations, business and industry about reducing GHG emissions.
- Replace traffic lights, street lights, and other electrical uses to energy efficient bulbs and appliances.
- Purchase Energy Star equipment and appliances for public agency use.
- Incorporate on-site renewable energy production, including installation of photovoltaic cells or other solar options.
- Execute an Energy Savings Performance Contract with a private entity to retrofit public buildings. This type of contract allows the private entity to fund all energy improvements in exchange for a share of the energy savings over a period of time.
- Design, build, and operate schools that meet the Collaborative for High Performance Schools (CHPS) best practices.
- Retrofit municipal water and wastewater systems with energy efficient motors, pumps and other equipment, and recover wastewater treatment methane for energy production.
- Convert landfill gas into energy sources for use in fueling vehicles, operating equipment, and heating buildings.
- Purchase government vehicles and buses that use alternatives fuels or technology, such as electric hybrids, biodiesel, and ethanol. Where feasible, require fleet vehicles to be low emission vehicles. Promote the use of these vehicles in the general community.
- Offer government incentives to private businesses for developing buildings with energy and water efficient features and recycled materials. The incentives can include expedited plan checks and reduced permit fees.
- Offer rebates and low-interest loans to residents that make energy-saving improvements on their homes.

- Create bicycle lanes and walking paths directed to the location of schools, parks and other destination points.

PROGRAMS TO REDUCE VEHICLE MILES TRAVELED

- Offer government employees financial incentives to carpool, use public transportation, or use other modes of travel for daily commutes.
- Encourage large businesses to develop commute trip reduction plans that encourage employees who commute alone to consider alternative transportation modes.
- Develop shuttle systems around business district parking garages to reduce congestion and create shorter commutes.
- Create an online ridesharing program that matches potential carpoolers immediately through email.
- Develop a Safe Routes to School program that allows and promotes bicycling and walking to school.

PROGRAMS TO REDUCE SOLID WASTE

- Create incentives to increase recycling and reduce generation of solid waste by residential users.
- Implement a Construction and Demolition Waste Recycling Ordinance to reduce the solid waste created by new development.
- Add residential/commercial food waste collection to existing greenwaste collection programs.

CEQA GUIDELINES

SECTIONS PROPOSED TO BE ADDED OR AMENDED

PROPOSED AMENDMENTS TO 14 SECTIONS

OF THE CEQA GUIDELINES

ARE INDICATED BY REDLINE/STRIKEOUT TEXT

OPR proposes that the Resources Agency amend or add the following fourteen (14) sections of the State CEQA Guidelines. The complete text of each section is provided below with strikeouts to indicate deletions and underlines to indicate additions.

15064. Determining the Significance of the Environmental Effects Caused by a Project

(a) Determining whether a project may have a significant effect plays a critical role in the CEQA process.

(1) If there is substantial evidence, in light of the whole record before a lead agency, that a project may have a significant effect on the environment, the agency shall prepare a draft EIR.

(2) When a final EIR identifies one or more significant effects, the Lead Agency and each Responsible Agency shall make a finding under Section 15091 for each significant effect and may need to make a statement of overriding considerations under Section 15093 for the project.

(b) The determination of whether a project may have a significant effect on the environment calls for careful judgment on the part of the public agency involved, based to the extent possible on scientific and factual data. An ironclad definition of significant effect is not always possible because the significance of an activity may vary with the setting. For example, an activity which may not be significant in an urban area may be significant in a rural area.

(c) In determining whether an effect will be adverse or beneficial, the Lead Agency shall consider the views held by members of the public in all areas affected as expressed in the whole record before the lead agency. Before requiring the preparation of an EIR, the Lead Agency must still determine whether environmental change itself might be substantial.

(d) In evaluating the significance of the environmental effect of a project, the Lead Agency shall consider direct physical changes in the environment which may be caused by the project and reasonably foreseeable indirect physical changes in the environment which may be caused by the project.

(1) A direct physical change in the environment is a physical change in the environment which is caused by and immediately related to the project. Examples of direct physical changes in the environment are the dust, noise, and traffic of heavy equipment that would result from construction of a sewage treatment plant and possible odors from operation of the plant.

(2) An indirect physical change in the environment is a physical change in the environment which is not immediately related to the project, but which is caused indirectly by the project. If a direct physical change in the environment in turn causes another change in the environment, then the other change is an indirect physical change in the environment. For example, the construction of a new sewage treatment plant may facilitate population growth in the service area due to the increase in sewage treatment capacity and may lead to an increase in air pollution.

(3) An indirect physical change is to be considered only if that change is a reasonably foreseeable impact which may be caused by the project. A change which is speculative or unlikely to occur is not reasonably foreseeable.

(e) Economic and social changes resulting from a project shall not be treated as significant effects on the environment. Economic or social changes may be used, however, to determine that a physical change shall be regarded as a significant effect on the environment. Where a physical change is caused by economic or social effects of a project, the physical change may be regarded as a significant effect in the same manner as any other physical change resulting from the project. Alternatively, economic and social effects of a physical change may be used to determine that the physical change is a significant effect on the environment. If the physical change causes adverse economic or social effects on people, those adverse effects may be used as a factor in determining whether the physical change is significant. For example, if a project would cause overcrowding of a public facility and the overcrowding causes an adverse effect on people, the overcrowding would be regarded as a significant effect.

(f) The decision as to whether a project may have one or more significant effects shall be based on substantial evidence in the record of the lead agency.

(1) If the lead agency determines there is substantial evidence in the record that the project may have a significant effect on the environment, the lead agency shall prepare an EIR (Friends of B Street v. City of Hayward (1980) 106 Cal.App.3d 988). Said another way, if a lead agency is presented with a fair argument that a project may have a significant effect on the environment, the lead agency shall prepare an EIR even though it may also be presented with other substantial evidence that the project will not have a significant effect (No Oil, Inc. v. City of Los Angeles (1974) 13 Cal.3d 68).

(2) If the lead agency determines there is substantial evidence in the record that the project may have a significant effect on the environment but the lead agency determines that revisions in the project plans or proposals made by, or agreed to by, the applicant would avoid the effects or mitigate the effects to a point where clearly no significant effect on the environment would occur and there is no substantial evidence in light of the whole record before the public agency that the project, as revised, may have a significant effect on the environment then a mitigated negative declaration shall be prepared.

(3) If the lead agency determines there is no substantial evidence that the project may have a significant effect on the environment, the lead agency shall prepare a negative declaration (Friends of B Street v. City of Hayward (1980) 106 Cal.App. 3d 988).

(4) The existence of public controversy over the environmental effects of a project will not require preparation of an EIR if there is no substantial evidence before the agency that the project may have a significant effect on the environment.

(5) Argument, speculation, unsubstantiated opinion or narrative, or evidence that is clearly inaccurate or erroneous, or evidence that is not credible, shall not constitute substantial evidence.

Substantial evidence shall include facts, reasonable assumptions predicated upon facts, and expert opinion supported by facts.

(6) Evidence of economic and social impacts that do not contribute to or are not caused by physical changes in the environment is not substantial evidence that the project may have a significant effect on the environment.

(7) The provisions of sections 15162, 15163, and 15164 apply when the project being analyzed is a change to, or further approval for, a project for which an EIR or negative declaration was previously certified or adopted (e.g. a tentative subdivision, conditional use permit). Under case law, the fair argument standard does not apply to determinations of significance pursuant to sections 15162, 15163, and 15164.

(g) After application of the principles set forth above in Section 15064(f)(g), and in marginal cases where it is not clear whether there is substantial evidence that a project may have a significant effect on the environment, the lead agency shall be guided by the following principle: If there is disagreement among expert opinion supported by facts over the significance of an effect on the environment, the Lead Agency shall treat the effect as significant and shall prepare an EIR.

(h)(1) When assessing whether a cumulative effect requires an EIR, the lead agency shall consider whether the cumulative impact is significant and whether the effects of the project are cumulatively considerable. An EIR must be prepared if the cumulative impact may be significant and the project's incremental effect, though individually limited, is cumulatively considerable. "Cumulatively considerable" means that the incremental effects of an individual project are significant when viewed in connection with the effects of past projects, the effects of other current projects, and the effects of probable future projects.

(2) A lead agency may determine in an initial study that a project's contribution to a significant cumulative impact will be rendered less than cumulatively considerable and thus is not significant. When a project might contribute to a significant cumulative impact, but the contribution will be rendered less than cumulatively considerable through mitigation measures set forth in a mitigated negative declaration, the initial study shall briefly indicate and explain how the contribution has been rendered less than cumulatively considerable.

(3) A lead agency may determine that a project's incremental contribution to a cumulative effect is not cumulatively considerable if the project will comply with the requirements in a previously approved plan or mitigation program (including, but not limited to, water quality control plan, air quality attainment or maintenance plan, integrated waste management plan, habitat conservation plan, natural community conservation plan, plans or regulations for the reduction of greenhouse gas emissions) which provides specific requirements that will avoid or substantially lessen the cumulative problem ~~(e.g., water quality control plan, air quality attainment or maintenance plan, integrated waste management plan)~~ within the geographic area in which the project is located. Such plans or programs must be specified in law or adopted by the public agency with jurisdiction over the affected resources through a public review process to implement, interpret, or make specific the law enforced or administered by the public agency. When relying on a plan

or program, the lead agency should explain how the particular requirements in the plan or program ensure that the project's incremental contribution to the cumulative effect is not cumulatively considerable. If there is substantial evidence that the possible effects of a particular project are still cumulatively considerable notwithstanding that the project complies with the specified plan or mitigation program addressing the cumulative problem, an EIR must be prepared for the project.

(4) The mere existence of significant cumulative impacts caused by other projects alone shall not constitute substantial evidence that the proposed project's incremental effects are cumulatively considerable.

Note: Authority cited: Section 21083, Public Resources Code. Reference: Sections 21003, 21065, 21068, 21080, 21082, 21082.1, 21082.2, 21083 and 21100, Public Resources Code; No Oil, Inc. v. City of Los Angeles (1974) 13 Cal.3d 68; San Joaquin Raptor/Wildlife Center v. County of Stanislaus (1996) 42 Cal.App.4th 608; Gentry v. City of Murrieta (1995) 36 Cal.App.4th 1359; Laurel Heights Improvement Assn. v. Regents of the University of California (1993) 6 Cal.4th 1112; and Communities for a Better Environment v. California Resources Agency (2002) 103 Cal.App.4th 98.

15064.4. Determining the Significance of Impacts from Greenhouse Gas Emissions

(a) The determination of the significance of greenhouse gas emissions calls for a careful judgment by the lead agency consistent with the provisions in section 15064. A lead agency should make a good-faith effort, based on available information, to describe, calculate or estimate the amount of greenhouse gas emissions resulting from a project. A lead agency shall have discretion to determine, in the context of a particular project, whether to:

(1) Use a model or methodology to quantify greenhouse gas emissions resulting from a project, and which model or methodology to use. The lead agency has discretion to select the model it considers most appropriate provided it supports its decision with substantial evidence. The lead agency should explain the limitations of the particular model or methodology selected for use; or

(2) Rely on a qualitative analysis or performance based standards.

(b) A lead agency may consider the following when assessing the significance of impacts from greenhouse gas emissions on the environment:

(1) The extent to which the project may increase or reduce greenhouse gas emissions as compared to the existing environmental setting;

(2) Whether the project emissions exceed a threshold of significance that the lead agency determines applies to the project.

(3) The extent to which the project complies with regulations or requirements adopted to implement a statewide, regional, or local plan for the reduction or mitigation of greenhouse gas emissions. Such regulations or requirements must be adopted by the relevant public agency

through a public review process and must include specific requirements that reduce or mitigate the project's incremental contribution of greenhouse gas emissions. If there is substantial evidence that the possible effects of a particular project are still cumulatively considerable notwithstanding compliance with the adopted regulations or requirements, an EIR must be prepared for the project.

15064.7. Thresholds of Significance

(a) Each public agency is encouraged to develop and publish thresholds of significance that the agency uses in the determination of the significance of environmental effects. A threshold of significance is an identifiable quantitative, qualitative or performance level of a particular environmental effect, non-compliance with which means the effect will normally be determined to be significant by the agency and compliance with which means the effect normally will be determined to be less than significant.

(b) Thresholds of significance to be adopted for general use as part of the lead agency's environmental review process must be adopted by ordinance, resolution, rule, or regulation, and developed through a public review process and be supported by substantial evidence.

(c) When adopting thresholds of significance, a lead agency may consider thresholds of significance previously adopted or recommended by other public agencies, or recommended by experts, provided the decision of the lead agency to adopt such thresholds is supported by substantial evidence.

Note: Authority: Section 21083, Public Resources Code. Reference: Sections 21082 and 21083, Public Resources Code.

15065. Mandatory Findings of Significance

(a) A lead agency shall find that a project may have a significant effect on the environment and thereby require an EIR to be prepared for the project where there is substantial evidence, in light of the whole record, that any of the following conditions may occur:

(1) The project has the potential to: substantially degrade the quality of the environment; substantially reduce the habitat of a fish or wildlife species; cause a fish or wildlife population to drop below self-sustaining levels; threaten to eliminate a plant or animal community; substantially reduce the number or restrict the range of an endangered, rare or threatened species; or eliminate important examples of the major periods of California history or prehistory.

(2) The project has the potential to achieve short-term environmental goals to the disadvantage of long-term environmental goals.

(3) The project has possible environmental effects that are individually limited but cumulatively considerable. "Cumulatively considerable" means that the incremental effects of an individual project are significant when viewed in connection with the effects of past projects, the effects of other current projects, and the effects of probable future projects.

(4) The environmental effects of a project will cause substantial adverse effects on human beings, either directly or indirectly.

(b)(1) Where, prior to the commencement of ~~preliminary~~ public review of an environmental document, a project proponent agrees to mitigation measures or project modifications that would avoid any significant effect on the environment specified by subdivision (a) or would mitigate the significant effect to a point where clearly no significant effect on the environment would occur, a lead agency need not prepare an environmental impact report solely because, without mitigation, the environmental effects at issue would have been significant.

(2) Furthermore, where a proposed project has the potential to substantially reduce the number or restrict the range of an endangered, rare or threatened species, the lead agency need not prepare an EIR solely because of such an effect, if:

(A) the project proponent is bound to implement mitigation requirements relating to such species and habitat pursuant to an approved habitat conservation plan or natural community conservation plan;

(B) the state or federal agency approved the habitat conservation plan or natural community conservation plan in reliance on an environmental impact report or environmental impact statement; and

(C) 1. such requirements avoid any net loss of habitat and net reduction in number of the affected species, or

2. such requirements preserve, restore, or enhance sufficient habitat to mitigate the reduction in habitat and number of the affected species to below a level of significance.

(c) Following the decision to prepare an EIR, if a lead agency determines that any of the conditions specified by subdivision (a) will occur, such a determination shall apply to:

(1) the identification of effects to be analyzed in depth in the environmental impact report or the functional equivalent thereof,

(2) the requirement to make detailed findings on the feasibility of alternatives or mitigation measures to substantially lessen or avoid the significant effects on the environment,

(3) when found to be feasible, the making of changes in the project to substantially lessen or avoid the significant effects on the environment, and

(4) where necessary, the requirement to adopt a statement of overriding considerations.

Note: Authority cited: Section 21083, Public Resources Code. Reference: Sections 21001(c), 21082.2, and 21083, Public Resources Code; San Joaquin Raptor/Wildlife Center v. County of Stanislaus (1996) 42 Cal.App.4th 608; Los Angeles Unified School District v. City of Los

Angeles (1997) 58 Cal.App.4th 1019, 1024; and Communities for a Better Environment v. California Resources Agency (2002) 103 Cal.App.4th 98.

15086. Consultation Concerning Draft EIR

(a) The Lead Agency shall consult with and request comments on the draft EIR from:

(1) Responsible Agencies,

(2) Trustee agencies with resources affected by the project, and

(3) Any other state, federal, and local agencies which have jurisdiction by law with respect to the project or which exercise authority over resources which may be affected by the project, including water agencies consulted pursuant to section 15083.5.

(4) Any city or county which borders on a city or county within which the project is located.

(5) For a project of statewide, regional, or areawide significance, the transportation planning agencies and public agencies which have transportation facilities within their jurisdictions which could be affected by the project. "Transportation facilities" includes: major local arterials and public transit within five miles of the project site, and freeways, highways and rail transit service within 10 miles of the project site.

(6) For a state lead agency when the EIR is being prepared for a highway or freeway project, the ~~State~~ California Air Resources Board as to the air pollution impact of the potential vehicular use of the highway or freeway and if a non-attainment area, the local air quality management district for a determination of conformity with the air quality management plan.

(7) For a subdivision project located within one mile of a facility of the State Water Resources Development System, the California Department of Water Resources.

(b) The lead agency may consult directly with:

(1) Any person who has special expertise with respect to any environmental impact involved.

(2) Any member of the public who has filed a written request for notice with the lead agency or the clerk of the governing body.

(3) Any person identified by the applicant whom the applicant believes will be concerned with the environmental effects of the project.

(c) A responsible agency or other public agency shall only make substantive comments regarding those activities involved in the project that are within an area of expertise of the agency or which are required to be carried out or approved by the responsible agency. Those comments shall be supported by specific documentation.

(d) Prior to the close of the public review period, a responsible agency or trustee agency which has identified what that agency considers to be significant environmental effects shall advise the lead agency of those effects. As to those effects relevant to its decision, if any, on the project, the responsible or trustee agency shall either submit to the lead agency complete and detailed performance objectives for mitigation measures addressing those effects or refer the lead agency to appropriate, readily available guidelines or reference documents concerning mitigation measures. If the responsible or trustee agency is not aware of mitigation measures that address identified effects, the responsible or trustee agency shall so state.

Note: Authority cited: Section 21083, Public Resources Code; Reference: Sections 21081.6, 21092.4, 21092.5, 21104 and 21153, Public Resources Code.

15093. Statement of Overriding Considerations

(a) CEQA requires the decision-making agency to balance, as applicable, the economic, legal, social, technological, or other benefits of a proposed project against its unavoidable environmental risks when determining whether to approve the project. If the specific economic, legal, social, technological, or other benefits of a proposed project outweigh the unavoidable adverse environmental effects, the adverse environmental effects may be considered "acceptable."

(b) When the lead agency approves a project which will result in the occurrence of significant effects which are identified in the final EIR but are not avoided or substantially lessened, the agency shall state in writing the specific reasons to support its action based on the final EIR and/or other information in the record. The statement of overriding considerations shall be supported by substantial evidence in the record.

(c) If an agency makes a statement of overriding considerations, the statement should be included in the record of the project approval and should be mentioned in the notice of determination. This statement does not substitute for, and shall be in addition to, findings required pursuant to Section 15091.

(d) When an agency makes a statement of overriding considerations, the agency may consider adverse environmental effects in the context of region-wide or statewide environmental benefits.

Note: Authority cited: Section 21083, Public Resources Code; Reference: Sections 21002 and 21081, Public Resources Code; San Francisco Ecology Center v. City and County of San Francisco (1975) 48 Cal.App.3d 584; City of Carmel-by-the-Sea v. Board of Supervisors (1977) 71 Cal.App.3d 84; Sierra Club v. Contra Costa County (1992) 10 Cal.App.4th 1212; Citizens for Quality Growth v. City of Mount Shasta (1988) 198 Cal.App.3d 433.

15125. Environmental Setting

(a) An EIR must include a description of the physical environmental conditions in the vicinity of the project, as they exist at the time the notice of preparation is published, or if no notice of preparation is published, at the time environmental analysis is commenced, from both a local and regional perspective. This environmental setting will normally constitute the baseline physical conditions by which a lead agency determines whether an impact is significant. The description of the environmental setting shall be no longer than is necessary to an understanding of the significant effects of the proposed project and its alternatives.

(b) When preparing an EIR for a plan for the reuse of a military base, lead agencies should refer to the special application of the principle of baseline conditions for determining significant impacts contained in Section 15229.

(c) Knowledge of the regional setting is critical to the assessment of environmental impacts. Special emphasis should be placed on environmental resources that are rare or unique to that region and would be affected by the project. The EIR must demonstrate that the significant environmental impacts of the proposed project were adequately investigated and discussed and it must permit the significant effects of the project to be considered in the full environmental context.

(d) The EIR shall discuss any inconsistencies between the proposed project and applicable general plans, specific plans and regional plans. Such regional plans include, but are not limited to, the applicable air quality attainment or maintenance plan or State Implementation Plan, area-wide waste treatment and water quality control plans, regional transportation plans, regional housing allocation plans, regional blueprint plans, greenhouse gas reduction plans, habitat conservation plans, natural community conservation plans and regional land use plans for the protection of the Coastal Zone, Lake Tahoe Basin, San Francisco Bay, and Santa Monica Mountains.

(e) Where a proposed project is compared with an adopted plan, the analysis shall examine the existing physical conditions at the time the notice of preparation is published, or if no notice of preparation is published, at the time environmental analysis is commenced as well as the potential future conditions discussed in the plan.

Note: Authority cited: Section 21083, Public Resources Code; Reference: Sections 21061 and 21100, Public Resources Code; E.P.I.C. v. County of El Dorado (1982) 131 Cal.App.3d 350; San Joaquin Raptor/Wildlife Rescue Center v. County of Stanislaus (1994) 27 Cal.App.4th 713; Bloom v. McGurk (1994) 26 Cal.App.4th 1307.

15126.2. Consideration and Discussion of Significant Environmental Impacts.

(a) The Significant Environmental Effects of the Proposed Project. An EIR shall identify and focus on the significant environmental effects of the proposed project. In assessing the impact of a proposed project on the environment, the lead agency should normally limit its examination to changes in the existing physical conditions in the affected area as they exist at the time the notice of preparation is published, or where no notice of preparation is published, at the time environmental analysis is commenced. Direct and indirect significant effects of the project on the environment shall be clearly identified and described, giving due consideration to both the short-term and long-term effects. The discussion should include relevant specifics of the area, the resources involved, physical changes, alterations to ecological systems, and changes induced in population distribution, population concentration, the human use of the land (including commercial and residential development), health and safety problems caused by the physical changes, and other aspects of the resource base such as water, historical resources, scenic quality, and public services. The EIR shall also analyze any significant environmental effects the project might cause by bringing development and people into the area affected. For example, an EIR on a subdivision astride an active fault line should identify as a significant effect the seismic hazard to future occupants of the subdivision. The subdivision would have the effect of attracting people to the location and exposing them to the hazards found there.

(b) Significant Environmental Effects Which Cannot be Avoided if the Proposed Project is Implemented. Describe any significant impacts, including those which can be mitigated but not reduced to a level of insignificance. Where there are impacts that cannot be alleviated without imposing an alternative design, their implications and the reasons why the project is being proposed, notwithstanding their effect, should be described.

(c) Significant Irreversible Environmental Changes Which Would be Caused by the Proposed Project Should it be Implemented. Uses of nonrenewable resources during the initial and continued phases of the project may be irreversible since a large commitment of such resources makes removal or nonuse thereafter unlikely. Primary impacts and, particularly, secondary impacts (such as highway improvement which provides access to a previously inaccessible area) generally commit future generations to similar uses. Also irreversible damage can result from environmental accidents associated with the project. Irretrievable commitments of resources should be evaluated to assure that such current consumption is justified. (See Public Resources Code section 21100.1 and Title 14, California Code of Regulations, section 15127 for limitations to applicability of this requirement.)

(d) Growth-Inducing Impact of the Proposed Project. Discuss the ways in which the proposed project could foster economic or population growth, or the construction of additional housing, either directly or indirectly, in the surrounding environment. Included in this are projects which would remove obstacles to population growth (a major expansion of a waste water treatment plant might, for example, allow for more construction in service areas). Increases in the population may tax existing community service facilities, requiring construction of new facilities that could cause significant environmental effects. Also discuss the characteristic of some projects which may encourage and facilitate other activities that could significantly affect the environment, either individually or cumulatively. It must not be assumed that growth in any area is necessarily beneficial, detrimental, or of little significance to the environment.

Note: Authority cited: Section 21083, Public Resources Code. Reference: Sections 21002, 21003, and 21100, Public Resources Code; Citizens of Goleta Valley v. Board of Supervisors, (1990) 52 Cal.3d 553; Laurel Heights Improvement Association v. Regents of the University of California, (1988) 47 Cal.3d 376; Gentry v. City of Murrieta (1995) 36 Cal.App.4th 1359; and Laurel Heights Improvement Association v. Regents of the University of California (1993) 6 Cal.4th 1112; Goleta Union School Dist. v. Regents of the Univ. Of Calif (1995) 37 Cal. App.4th 1025.

15126.4. Consideration and Discussion of Mitigation Measures Proposed to Minimize Significant Effects.

(a) Mitigation Measures in General.

(1) An EIR shall describe feasible measures which could minimize significant adverse impacts, including where relevant, inefficient and unnecessary consumption of energy.

(A) The discussion of mitigation measures shall distinguish between the measures which are proposed by project proponents to be included in the project and other measures proposed by the lead, responsible or trustee agency or other persons which are not included but the lead agency determines could reasonably be expected to reduce adverse impacts if required as conditions of approving the project. This discussion shall identify mitigation measures for each significant environmental effect identified in the EIR.

(B) Where several measures are available to mitigate an impact, each should be discussed and the basis for selecting a particular measure should be identified. Formulation of mitigation measures should not be deferred until some future time. However, measures may specify performance standards which would mitigate the significant effect of the project and which may be accomplished in more than one specified way.

(C) Energy conservation measures, as well as other appropriate mitigation measures, shall be discussed when relevant. Examples of energy conservation measures are provided in Appendix F.

(D) If a mitigation measure would cause one or more significant effects in addition to those that would be caused by the project as proposed, the effects of the mitigation measure shall be discussed but in less detail than the significant effects of the project as proposed. (Stevens v. City of Glendale(1981) 125 Cal.App.3d 986.)

(2) Mitigation measures must be fully enforceable through permit conditions, agreements, or other legally-binding instruments. In the case of the adoption of a plan, policy, regulation, or other public project, mitigation measures can be incorporated into the plan, policy, regulation, or project design.

(3) Mitigation measures are not required for effects which are not found to be significant.

(4) Mitigation measures must be consistent with all applicable constitutional requirements, including the following:

(A) There must be an essential nexus (i.e. connection) between the mitigation measure and a legitimate governmental interest. (Nollan v. California Coastal Commission, 483 U.S. 825 (1987)); and

(B) The mitigation measure must be "roughly proportional" to the impacts of the project. Dolan v. City of Tigard, 512 U.S. 374 (1994). Where the mitigation measure is an ad hoc exaction, it must be "roughly proportional" to the impacts of the project. (Ehrlich v. City of Culver City (1996) 12 Cal.4th 854).

(5) If the lead agency determines that a mitigation measure cannot be legally imposed, the measure need not be proposed or analyzed. Instead, the EIR may simply reference that fact and briefly explain the reasons underlying the lead agency's determination.

(b) Mitigation Measures Related to Impacts on Historical Resources.

(1) Where maintenance, repair, stabilization, rehabilitation, restoration, preservation, conservation or reconstruction of the historical resource will be conducted in a manner consistent with the Secretary of the Interior's Standards for the Treatment of Historic Properties with Guidelines for Preserving, Rehabilitating, Restoring, and Reconstructing Historic Buildings (1995), Weeks and Grimmer, the project's impact on the historical resource shall generally be considered mitigated below a level of significance and thus is not significant.

(2) In some circumstances, documentation of an historical resource, by way of historic narrative, photographs or architectural drawings, as mitigation for the effects of demolition of the resource will not mitigate the effects to a point where clearly no significant effect on the environment would occur.

(3) Public agencies should, whenever feasible, seek to avoid damaging effects on any historical resource of an archaeological nature. The following factors shall be considered and discussed in an EIR for a project involving such an archaeological site:

(A) Preservation in place is the preferred manner of mitigating impacts to archaeological sites. Preservation in place maintains the relationship between artifacts and the archaeological context. Preservation may also avoid conflict with religious or cultural values of groups associated with the site.

(B) Preservation in place may be accomplished by, but is not limited to, the following:

1. Planning construction to avoid archaeological sites;

2. Incorporation of sites within parks, greenspace, or other open space;

3. Covering the archaeological sites with a layer of chemically stable soil before building tennis courts, parking lots, or similar facilities on the site.

4. Deeding the site into a permanent conservation easement.

(C) When data recovery through excavation is the only feasible mitigation, a data recovery plan, which makes provisions for adequately recovering the scientifically consequential information from and about the historical resource, shall be prepared and adopted prior to any excavation being undertaken. Such studies shall be deposited with the California Historical Resources Regional Information Center. Archeological sites known to contain human remains shall be treated in accordance with the provisions of Section 7050.5 Health and Safety Code. If an artifact must be removed during project excavation or testing, curation may be an appropriate mitigation.

(D) Data recovery shall not be required for an historical resource if the lead agency determines that testing or studies already completed have adequately recovered the scientifically consequential information from and about the archaeological or historical resource, provided that the determination is documented in the EIR and that the studies are deposited with the California Historical Resources Regional Information Center.

(c) Mitigation Measures Related to Greenhouse Gas Emissions.

Consistent with section 15126.4(a), lead agencies shall consider feasible means of mitigating greenhouse gas emissions that may include, but not be limited to:

(1) Measures in an existing plan or mitigation program for the reduction of emissions that are required as part of the lead agency's decision;

(2) Reductions in emissions resulting from a project through implementation of project features, project design, or other measures, such as those described in Appendix F;

(3) Off-site measures, including offsets, to mitigate a project's emissions;

(4) Measures that sequester greenhouse gases; and

(5) In the case of the adoption of a plan, such as a general plan, long range development plan, or greenhouse gas reduction plan, mitigation may include the identification of specific measures that may be implemented on a project-by-project basis. Mitigation may also include the incorporation of specific measures or policies found in an adopted ordinance or regulation that reduces the cumulative effect of emissions.

Note: Authority: Section 21083, Public Resources Code. Reference: Sections 5020.5, 21002, 21003, 21100 and 21084.1, Public Resources Code; Citizens of Goleta Valley v. Board of Supervisors (1990) 52 Cal.3d 553; Laurel Heights Improvement Association v. Regents of the University of California (1988) 47 Cal.3d 376; Gentry v. City of Murrieta (1995) 36 Cal.App.4th 1359; Laurel Heights Improvement Association v. Regents of the University of California (1993) 6 Cal.4th 1112; and Sacramento Old City Assn. v. City Council of Sacramento (1991) 229 Cal.App.3d 1011.

15130. Discussion of Cumulative Impacts

(a) An EIR shall discuss cumulative impacts of a project when the project's incremental effect is cumulatively considerable, as defined in section 15065(a)(3). Where a lead agency is examining a project with an incremental effect that is not "cumulatively considerable," a lead agency need not consider that effect significant, but shall briefly describe its basis for concluding that the incremental effect is not cumulatively considerable.

(1) As defined in Section 15355, a cumulative impact consists of an impact which is created as a result of the combination of the project evaluated in the EIR together with other projects causing related impacts. An EIR should not discuss impacts which do not result in part from the project evaluated in the EIR.

(2) When the combined cumulative impact associated with the project's incremental effect and the effects of other projects is not significant, the EIR shall briefly indicate why the cumulative impact is not significant and is not discussed in further detail in the EIR. A lead agency shall identify facts and analysis supporting the lead agency's conclusion that the cumulative impact is less than significant.

(3) An EIR may determine that a project's contribution to a significant cumulative impact will be rendered less than cumulatively considerable and thus is not significant. A project's contribution is less than cumulatively considerable if the project is required to implement or fund its fair share of a mitigation measure or measures designed to alleviate the cumulative impact. The lead agency shall identify facts and analysis supporting its conclusion that the contribution will be rendered less than cumulatively considerable.

(b) The discussion of cumulative impacts shall reflect the severity of the impacts and their likelihood of occurrence, but the discussion need not provide as great detail as is provided for the effects attributable to the project alone. The discussion should be guided by standards of practicality and reasonableness, and should focus on the cumulative impact to which the identified other projects contribute rather than the attributes of other projects which do not contribute to the cumulative impact. The following elements are necessary to an adequate discussion of significant cumulative impacts:

(1) Either:

(A) A list of past, present, and probable future projects producing related or cumulative impacts, including, if necessary, those projects outside the control of the agency, or

(B) A summary of projections contained in an adopted ~~general plan or related planning document, or in a prior environmental document which has been adopted or certified, which described or evaluated regional or areawide conditions contributing to the cumulative impact~~ local, regional or statewide plan, or related planning document, that describes or evaluates conditions contributing to the cumulative effect. Such plans may include: a general plan, regional transportation plan, or greenhouse gas reduction plan. A summary of projections may also be contained in an adopted or certified prior environmental document for such a plan. Such projections may be supplemented with additional information such as a regional modeling program. Any such ~~planning~~ document shall be referenced and made available to the public at a location specified by the lead agency.

(2) When utilizing a list, as suggested in paragraph (1) of subdivision (b), factors to consider when determining whether to include a related project should include the nature of each environmental resource being examined, the location of the project and its type. Location may be important, for example, when water quality impacts are at issue since projects outside the

watershed would probably not contribute to a cumulative effect. Project type may be important, for example, when the impact is specialized, such as a particular air pollutant or mode of traffic.

(3) Lead agencies should define the geographic scope of the area affected by the cumulative effect and provide a reasonable explanation for the geographic limitation used.

(4) A summary of the expected environmental effects to be produced by those projects with specific reference to additional information stating where that information is available; and

(5) A reasonable analysis of the cumulative impacts of the relevant projects. An EIR shall examine reasonable, feasible options for mitigating or avoiding the project's contribution to any significant cumulative effects.

(c) With some projects, the only feasible mitigation for cumulative impacts may involve the adoption of ordinances or regulations rather than the imposition of conditions on a project-by-project basis.

(d) Previously approved land use documents including, but not limited to, general plans, specific plans, regional transportation plans, greenhouse gas reduction plans, and local coastal plans may be used in cumulative impact analysis. A pertinent discussion of cumulative impacts contained in one or more previously certified EIRs may be incorporated by reference pursuant to the provisions for tiering and program EIRs. No further cumulative impacts analysis is required when a project is consistent with a general, specific, master or comparable programmatic plan where the lead agency determines that the regional or areawide cumulative impacts of the proposed project have already been adequately addressed, as defined in section 15152(f), in a certified EIR for that plan.

(e) If a cumulative impact was adequately addressed in a prior EIR for a community plan, zoning action, or general plan, and the project is consistent with that plan or action, then an EIR for such a project should not further analyze that cumulative impact, as provided in Section 15183(j).

(f) An EIR shall analyze greenhouse gas emissions resulting from a proposed project when the incremental contribution of those emissions may be cumulatively considerable.

Note: Authority cited: Section 21083, Public Resources Code. Reference: Sections 21083(b), 21093, 21094 and 21100, Public Resources Code; Whitman v. Board of Supervisors, (1979) 88 Cal. App. 3d 397; San Franciscans for Reasonable Growth v. City and County of San Francisco (1984) 151 Cal.App.3d 61; Kings County Farm Bureau v. City of Hanford (1990) 221 Cal.App.3d 692; Laurel Heights Homeowners Association v. Regents of the University of California (1988) 47 Cal.3d 376; Sierra Club v. Gilroy (1990) 220 Cal.App.3d 30; Citizens to Preserve the Ojai v. County of Ventura (1985) 176 Cal.App.3d 421; Concerned Citizens of South Cent. Los Angeles v. Los Angeles Unified Sch. Dist. (1994) 24 Cal.App.4th 826; Las Virgenes Homeowners Fed'n v. County of Los Angeles (1986) 177 Cal.App.3d 300; San Joaquin Raptor/Wildlife Rescue Ctr v. County of Stanislaus (1994) 27 Cal.App.4th 713; Fort Mojave Indian Tribe v. Cal. Dept. Of Health Services (1995) 38 Cal.App.4th 1574; and Communities for a Better Environment v. California Resources Agency (2002) 103 Cal.App.4th 98.

15150. Incorporation by Reference

(a) An EIR or Negative Declaration may incorporate by reference all or portions of another document which is a matter of public record or is generally available to the public. Where all or part of another document is incorporated by reference, the incorporated language shall be considered to be set forth in full as part of the text of the EIR or Negative Declaration.

(b) Where part of another document is incorporated by reference, such other document shall be made available to the public for inspection at a public place or public building. The EIR or Negative Declaration shall state where the incorporated documents will be available for inspection. At a minimum, the incorporated document shall be made available to the public in an office of the Lead Agency in the county where the project would be carried out or in one or more public buildings such as county offices or public libraries if the Lead Agency does not have an office in the county.

(c) Where an EIR or Negative Declaration uses incorporation by reference, the incorporated part of the referenced document shall be briefly summarized where possible or briefly described if the data or information cannot be summarized. The relationship between the incorporated part of the referenced document and the EIR shall be described.

(d) Where an agency incorporates information from an EIR that has previously been reviewed through the state review system, the state identification number of the incorporated document should be included in the summary or designation described in subdivision (c).

(e) Examples of materials that may be incorporated by reference include but are not limited to:

(1) A description of the environmental setting from another EIR.

(2) A description of the air pollution problems prepared by an air pollution control agency concerning a process involved in the project.

(3) A description of the city or county general plan that applies to the location of the project.

(4) A description of the effects of greenhouse gas emissions on the environment.

(f) Incorporation by reference is most appropriate for including long, descriptive, or technical materials that provide general background but do not contribute directly to the analysis of the problem at hand.

Note: Authority cited: Section 21083, Public Resources Code; Reference Sections 21003, 21061, and 21100, Public Resources Code.

15183. Projects Consistent with a Community Plan or Zoning

(a) CEQA mandates that projects which are consistent with the development density established by existing zoning, community plan, or general plan policies for which an EIR was certified shall not require additional environmental review, except as might be necessary to examine whether there are project-specific significant effects which are peculiar to the project or its site. This streamlines the review of such projects and reduces the need to prepare repetitive environmental studies.

(b) In approving a project meeting the requirements of this section, a public agency shall limit its examination of environmental effects to those which the agency determines, in an initial study or other analysis:

(1) Are peculiar to the project or the parcel on which the project would be located,

(2) Were not analyzed as significant effects in a prior EIR on the zoning action, general plan, or community plan, with which the project is consistent,

(3) Are potentially significant off-site impacts and cumulative impacts which were not discussed in the prior EIR prepared for the general plan, community plan or zoning action, or

(4) Are previously identified significant effects which, as a result of substantial new information which was not known at the time the EIR was certified, are determined to have a more severe adverse impact than discussed in the prior EIR.

(c) If an impact is not peculiar to the parcel or to the project, has been addressed as a significant effect in the prior EIR, or can be substantially mitigated by the imposition of uniformly applied development policies or standards, as contemplated by subdivision (e) below, then an additional EIR need not be prepared for the project solely on the basis of that impact.

(d) This section shall apply only to projects which meet the following conditions:

(1) The project is consistent with:

(A) A community plan adopted as part of a general plan,

(B) A zoning action which zoned or designated the parcel on which the project would be located to accommodate a particular density of development, or

(C) A general plan of a local agency, and

(2) An EIR was certified by the lead agency for the zoning action, the community plan, or the general plan.

(e) This section shall limit the analysis of only those significant environmental effects for which:

(1) Each public agency with authority to mitigate any of the significant effects on the environment identified in the planning or zoning action undertakes or requires others to undertake mitigation measures specified in the EIR which the lead agency found to be feasible, and

(2) The lead agency makes a finding at a public hearing as to whether the feasible mitigation measures will be undertaken.

(f) An effect of a project on the environment shall not be considered peculiar to the project or the parcel for the purposes of this section if uniformly applied development policies or standards have been previously adopted by the city or county with a finding that the development policies or standards will substantially mitigate that environmental effect when applied to future projects, unless substantial new information shows that the policies or standards will not substantially mitigate the environmental effect. The finding shall be based on substantial evidence which need not include an EIR. Such development policies or standards need not apply throughout the entire city or county, but can apply only within the zoning district in which the project is located, or within the area subject to the community plan on which the lead agency is relying. Moreover, such policies or standards need not be part of the general plan or any community plan, but can be found within another pertinent planning document such as a zoning ordinance. Where a city or county, in previously adopting uniformly applied development policies or standards for imposition on future projects, failed to make a finding as to whether such policies or standards would substantially mitigate the effects of future projects, the decisionmaking body of the city or county, prior to approving such a future project pursuant to this section, may hold a public hearing for the purpose of considering whether, as applied to the project, such standards or policies would substantially mitigate the effects of the project. Such a public hearing need only be held if the city or county decides to apply the standards or policies as permitted in this section.

(g) Examples of uniformly applied development policies or standards include, but are not limited to:

(1) Parking ordinances.

(2) Public access requirements.

(3) Grading ordinances.

(4) Hillside development ordinances.

(5) Flood plain ordinances.

(6) Habitat protection or conservation ordinances.

(7) View protection ordinances.

(8) Requirements for reducing greenhouse gas emissions, as set forth in an adopted land use plan, policy or regulation.

(h) An environmental effect shall not be considered peculiar to the project or parcel solely because no uniformly applied development policy or standard is applicable to it.

(i) Where the prior EIR relied upon by the lead agency was prepared for a general plan or community plan that meets the requirements of this section, any rezoning action consistent with the general plan or community plan shall be treated as a project subject to this section.

(1) "Community plan" is defined as a part of the general plan of a city or county which applies to a defined geographic portion of the total area included in the general plan, includes or references each of the mandatory elements specified in Section 65302 of the Government Code, and contains specific development policies and implementation measures which will apply those policies to each involved parcel.

(2) For purposes of this section, "consistent" means that the density of the proposed project is the same or less than the standard expressed for the involved parcel in the general plan, community plan or zoning action for which an EIR has been certified, and that the project complies with the density-related standards contained in that plan or zoning. Where the zoning ordinance refers to the general plan or community plan for its density standard, the project shall be consistent with the applicable plan.

(j) This section does not affect any requirement to analyze potentially significant offsite or cumulative impacts if those impacts were not adequately discussed in the prior EIR. If a significant offsite or cumulative impact was adequately discussed in the prior EIR, then this section may be used as a basis for excluding further analysis of that offsite or cumulative impact.

Note: Authority cited: Section 21083, Public Resources Code; Reference: Section 21083.3, Public Resources Code.

15183.5 Tiering and Streamlining the Analysis of Greenhouse Gas Emissions

(a) Lead agencies may analyze and mitigate the effects of greenhouse gas emissions at a programmatic level, such as in a general plan, a long range development plan, or a separate plan to reduce greenhouse gas emissions. Later project-specific environmental documents may tier and/or incorporate by reference that existing programmatic review. Project-specific environmental documents may rely on an EIR containing a programmatic analysis of greenhouse gas emissions as provided in section 15152 (tiering), 15168 (program EIRs), 15175-15179.5 (Master EIRs), 15182 (EIRs Prepared for Specific Plans), and 15183 (EIRs Prepared for General Plans, Community Plans, or Zoning).

(b) Greenhouse Gas Reduction Plans. Public agencies may choose to analyze and mitigate greenhouse gas emissions in a greenhouse gas reduction plan or similar document. A plan to reduce greenhouse gas emissions may be used in a cumulative impacts analysis as set forth below. Pursuant to sections 15064(h)(3) and 15130(d), a lead agency may determine that a project's incremental contribution to a cumulative effect is not cumulatively considerable if the project complies with the requirements in a previously adopted plan or mitigation program under specified circumstances.

(1) Plan Elements. A greenhouse gas emissions reduction plan may:

(A) Quantify greenhouse gas emissions, both existing and projected over a specified time period, resulting from activities within a defined geographic area;

(B) Establish a level, based on substantial evidence, below which the contribution to greenhouse gas emissions from activities covered by the plan would not be cumulatively considerable;

(C) Identify and analyze the greenhouse gas emissions resulting from specific actions or categories of actions anticipated within the geographic area;

(D) Specify measures or a group of measures, including performance standards, that substantial evidence demonstrates, if implemented on a project-by-project basis, would collectively achieve the specified emissions level;

(E) Establish a mechanism to monitor the plan's progress toward achieving the level and to require amendment if the plan is not achieving specified levels;

(F) Be adopted in a public process following environmental review.

(2) Use with Later Activities. A greenhouse gas reduction plan, once adopted following certification of an EIR, may be used in the cumulative impacts analysis of later projects. An environmental document that relies on a greenhouse gas reduction plan for a cumulative impacts analysis must identify those requirements specified in the plan that apply to the project, and, if those requirements are not otherwise binding and enforceable, incorporate those requirements as mitigation measures applicable to the project. If there is substantial evidence that the effects of a particular project may be cumulatively considerable notwithstanding the project's compliance with the specified requirements in the greenhouse gas reduction plan, an EIR must be prepared for the project.

(c) Special Situations. Consistent with Public Resources Code sections 21155.2 and 21159.28, certain residential and mixed use projects, and transit priority projects, as defined in section 21155, that are consistent with the general use designation, density, building intensity, and applicable policies specified for the project area in an applicable sustainable communities strategy or alternative planning strategy accepted by the California Air Resources Board need not analyze global warming impacts resulting from cars and light duty trucks. A lead agency should consider whether such projects may result in greenhouse gas emissions resulting from other sources, however, consistent with these Guidelines.

15364.5. Greenhouse Gas (Definition)

"Greenhouse gas" or "greenhouse gases" includes but is not limited to: carbon dioxide, methane, nitrous oxide, hydrofluorocarbons, perfluorocarbons and sulfur hexafluoride. (Reference: Health and Safety Code section 38505(g).)

CEQA GUIDELINES

APPENDIX F

ENERGY CONSERVATION

PROPOSED AMENDMENTS TO APPENDIX F

ARE INDICATED BY REDLINE/STRIKEOUT TEXT

CEQA Guidelines

Appendix F

ENERGY CONSERVATION

I. Introduction

The goal of conserving energy implies the wise and efficient use of energy. The means of achieving this goal include:

(1) decreasing overall per capita energy consumption,

(2) decreasing reliance on natural gas and oil, and

(3) increasing reliance on renewable energy sources.

In order to assure that energy implications are considered in project decisions, the California Environmental Quality Act requires that EIRs include a discussion of the potential energy impacts of proposed projects, with particular emphasis on avoiding or reducing inefficient, wasteful and unnecessary consumption of energy (see Public Resources Code section 21100(b)(3)). Energy conservation implies that a project's cost effectiveness be reviewed not only in dollars, but also in terms of energy requirements. For many projects, ~~lifetime~~ costs~~s~~ effectiveness may be determined more by energy efficiency than by initial dollar costs. A lead agency may consider the extent to which an energy source serving the project has already undergone environmental review that adequately analyzed and mitigated the effects of energy production.

II. EIR Contents

Potentially significant energy implications of a project ~~should~~ shall be considered in an EIR to the extent relevant and applicable to the project. The following list of energy impact possibilities and potential conservation measures is designed to assist in the preparation of an EIR. In many instances, specific items may not apply or additional items may be needed. Where items listed below are applicable or relevant to the project, they should be considered in the EIR.

A. Project Description may include the following items:

1. Energy consuming equipment and processes which will be used during construction, operation, and/or removal of the project. If appropriate, this discussion should consider the energy intensiveness of materials and equipment required for the project.

2. Total energy requirements of the project by fuel type and end use.

3. Energy conservation equipment and design features.

4. Identification of ~~Initial and lifecycle~~ energy ~~costs or~~ supplies that would serve the project.

5. Total estimated daily vehicle trips to be generated by the project and the additional energy consumed per trip by mode.

B. Environmental Setting may include existing energy supplies and energy use patterns in the region and locality.

C. Environmental Impacts may include:

1. The project's energy requirements and its energy use efficiencies by amount and fuel type for each stage of the project~~'s lifecycle~~ including construction, operation, maintenance and/or removal. If appropriate, the energy intensiveness of materials may be discussed.

2. The effects of the project on local and regional energy supplies and on requirements for additional capacity.

3. The effects of the project on peak and base period demands for electricity and other forms of energy.

4. The degree to which the project complies with existing energy standards.

5. The effects of the project on energy resources.

6. The project's projected transportation energy use requirements and its overall use of efficient transportation alternatives.

D. Mitigation Measures may include:

1. Potential measures to reduce wasteful, inefficient and unnecessary consumption of energy during construction, operation, maintenance and/or removal. The discussion should explain why certain measures were incorporated in the project and why other measures were dismissed.

2. The potential of siting, orientation, and design to minimize energy consumption, including transportation energy, water conservation and solid-waste reduction.

3. The potential for reducing peak energy demand.

4. Alternate fuels (particularly renewable ones) or energy systems.

5. Energy conservation which could result from recycling efforts.

E. Alternatives should be compared in terms of overall energy consumption and in terms of reducing wasteful, inefficient and unnecessary consumption of energy. F. Unavoidable Adverse

Effects may include wasteful, inefficient and unnecessary consumption of energy during the project construction, operation, maintenance and/or removal that cannot be feasibly mitigated.

G. Irreversible Commitment of Resources may include a discussion of how the project preempts future energy development or future energy conservation.

H. Short-Term Gains versus Long-Term Impacts can be compared by calculating the project's energy costs over the project's lifetime ~~of the project~~.

I. Growth Inducing Effects may include the estimated energy consumption of growth induced by the project.

CEQA GUIDELINES

APPENDIX G

INITIAL STUDY CHECKLIST

PROPOSED AMENDMENTS TO APPENDIX G

ARE INDICATED BY REDLINE/STRIKEOUT TEXT

CEQA Guidelines

Appendix G

Environmental Checklist Form

NOTE: The following is a sample form and may be tailored to satisfy individual agencies' needs and project circumstances. It may be used to meet the requirements for an initial study when the criteria set forth in the CEQA Guidelines have been met. Substantial evidence of potential impacts that are not listed on this form must also be considered. The sample questions in this form are intended to encourage thoughtful assessment of impacts, and do not necessarily represent thresholds of significance.

1. Project title: ____
2. Lead agency name and address:

____
____
____

3. Contact person and phone number: ____________________________
4. Project location: _______________________________________
5. Project sponsor's name and address:

____
____
____

6. General plan designation: ____________________
7. Zoning: __________________________
8. Description of project: (Describe the whole action involved, including but not limited to later phases of the project, and any secondary, support, or off-site features necessary for its implementation. Attach additional sheets if necessary.)

____
____
____

9. Surrounding land uses and setting: Briefly describe the project's surroundings:

____
____
____

10. Other public agencies whose approval is required (e.g., permits, financing approval, or participation agreement.)

____
____

ENVIRONMENTAL FACTORS POTENTIALLY AFFECTED:

The environmental factors checked below would be potentially affected by this project, involving at least one impact that is a "Potentially Significant Impact" as indicated by the checklist on the following pages.

Aesthetics
Agriculture and Forest Resources
Air Quality
Biological Resources
Cultural Resources
Geology/Soils
Greenhouse Gas Emissions
Hazards & Hazardous Materials
Hydrology/Water Quality
Land Use/Planning
Mineral Resources
Noise
Population/Housing
Public Services
Recreation
Transportation/Traffic
Utilities/Service Systems
Mandatory Findings of Significance

DETERMINATION: (To be completed by the Lead Agency)

On the basis of this initial evaluation:

I find that the proposed project COULD NOT have a significant effect on the environment, and a NEGATIVE DECLARATION will be prepared.

I find that although the proposed project could have a significant effect on the environment, there will not be a significant effect in this case because revisions in the project have been made by or agreed to by the project proponent. A MITIGATED NEGATIVE DECLARATION will be prepared.

I find that the proposed project MAY have a significant effect on the environment, and an ENVIRONMENTAL IMPACT REPORT is required.

I find that the proposed project MAY have a "potentially significant impact" or "potentially significant unless mitigated" impact on the environment, but at least one effect 1) has been adequately analyzed in an earlier document pursuant to applicable legal standards, and 2) has been addressed by mitigation measures based on the earlier analysis as described on attached sheets. An ENVIRONMENTAL IMPACT REPORT is required, but it must analyze only the effects that remain to be addressed.

I find that although the proposed project could have a significant effect on the environment, because all potentially significant effects (a) have been analyzed adequately in an earlier EIR or NEGATIVE DECLARATION pursuant to applicable standards, and (b) have been avoided or mitigated pursuant to that earlier EIR or NEGATIVE DECLARATION, including revisions or mitigation measures that are imposed upon the proposed project, nothing further is required.

Signature
Date
Printed Name

EVALUATION OF ENVIRONMENTAL IMPACTS:

1) A brief explanation is required for all answers except "No Impact" answers that are adequately supported by the information sources a lead agency cites in the parentheses following each question. A "No Impact" answer is adequately supported if the referenced information sources show that the impact simply does not apply to projects like the one involved (e.g., the project falls outside a fault rupture zone). A "No Impact" answer should be explained where it is based on project-specific factors as well as general standards (e.g., the project will not expose sensitive receptors to pollutants, based on a project-specific screening analysis).

2) All answers must take account of the whole action involved, including off-site as well as on-site, cumulative as well as project-level, indirect as well as direct, and construction as well as operational impacts.

3) Once the lead agency has determined that a particular physical impact may occur, then the checklist answers must indicate whether the impact is potentially significant, less than significant with mitigation, or less than significant. "Potentially Significant Impact" is appropriate if there is substantial evidence that an effect may be significant. If there are one or more "Potentially Significant Impact" entries when the determination is made, an EIR is required.

4) "Negative Declaration: Less Than Significant With Mitigation Incorporated" applies where the incorporation of mitigation measures has reduced an effect from "Potentially Significant Impact" to a "Less Than Significant Impact." The lead agency must describe the mitigation measures, and briefly explain how they reduce the effect to a less than significant level (mitigation measures from "Earlier Analyses," as described in (5) below, may be cross-referenced).

5) Earlier analyses may be used where, pursuant to the tiering, program EIR, or other CEQA process, an effect has been adequately analyzed in an earlier EIR or negative declaration. Section 15063(c)(3)(D). In this case, a brief discussion should identify the following:

a) Earlier Analysis Used. Identify and state where they are available for review.

b) Impacts Adequately Addressed. Identify which effects from the above checklist were within the scope of and adequately analyzed in an earlier document pursuant to applicable legal standards, and state whether such effects were addressed by mitigation measures based on the earlier analysis.

c) Mitigation Measures. For effects that are "Less than Significant with Mitigation Measures Incorporated," describe the mitigation measures which were incorporated or refined from the earlier document and the extent to which they address site-specific conditions for the project.

6) Lead agencies are encouraged to incorporate into the checklist references to information sources for potential impacts (e.g., general plans, zoning ordinances). Reference to a previously prepared or outside document should, where appropriate, include a reference to the page or pages where the statement is substantiated.

7) Supporting Information Sources: A source list should be attached, and other sources used or individuals contacted should be cited in the discussion.

8) This is only a suggested form, and lead agencies are free to use different formats; however, lead agencies should normally address the questions from this checklist that are relevant to a project's environmental effects in whatever format is selected.

9) The explanation of each issue should identify:

a) the significance criteria or threshold, if any, used to evaluate each question; and

b) the mitigation measure identified, if any, to reduce the impact to less than significance

SAMPLE QUESTIONS

I. AESTHETICS -- Would the project:

a) Have a substantial adverse effect on a scenic vista?

b) Substantially damage scenic resources, including, but not limited to, trees, rock outcroppings, and historic buildings within a state scenic highway?

c) Substantially degrade the existing visual character or quality of the site and its surroundings?

d) Create a new source of substantial light or glare which would adversely affect day or nighttime views in the area?

II. AGRICULTURE AND FOREST RESOURCES: In determining whether impacts to agricultural resources are significant environmental effects, lead agencies may refer to the California Agricultural Land Evaluation and Site Assessment Model (1997) prepared by the California Dept. of Conservation as an optional model to use in assessing impacts on agriculture and farmland. In determining whether impacts to forest resources, including timberland, are significant environmental effects, lead agencies may refer to information compiled by the California Department of Forestry and Fire Protection regarding the state's inventory of forest land, including the Forest and Range Assessment Project and the Forest Legacy Assessment project; and the forest carbon measurement methodology provided in the Forest Protocols adopted by the California Air Resources Board. Would the project:

a) Convert Prime Farmland, Unique Farmland, or Farmland of Statewide Importance (Farmland), as shown on the maps prepared pursuant to the Farmland Mapping and Monitoring Program of the California Resources Agency, to non-agricultural use?

b) Conflict with existing zoning for agricultural use, or a Williamson Act contract?

c) Conflict with existing zoning for, or cause rezoning of, forest land (as defined in Public Resources Code section 12220(g)) or timberland (as defined in Public Resources Code section 4526)?

d) Result in the loss of forest land or conversion of forest land to non-forest use?

e) Involve other changes in the existing environment which, due to their location or nature, could result in conversion of Farmland to non-agricultural use or conversion of forest land to non-forest use?

III. AIR QUALITY -- Where available, the significance criteria established by the applicable air quality management or air pollution control district may be relied upon to make the following determinations. Would the project:

a) Conflict with or obstruct implementation of the applicable air quality plan?

b) Violate any air quality standard or contribute substantially to an existing or projected air quality violation?

c) Result in a cumulatively considerable net increase of any criteria pollutant for which the project region is non-attainment under an applicable federal or state ambient air quality standard (including releasing emissions which exceed quantitative thresholds for ozone precursors)?

d) Expose sensitive receptors to substantial pollutant concentrations?

e) Create objectionable odors affecting a substantial number of people?

IV. BIOLOGICAL RESOURCES -- Would the project:

a) Have a substantial adverse effect, either directly or through habitat modifications, on any species identified as a candidate, sensitive, or special status species in local or regional plans, policies, or regulations, or by the California Department of Fish and Game or U.S. Fish and Wildlife Service?

b) Have a substantial adverse effect on any riparian habitat or other sensitive natural community identified in local or regional plans, policies, regulations or by the California Department of Fish and Game or US Fish and Wildlife Service?

c) Have a substantial adverse effect on federally protected wetlands as defined by Section 404 of the Clean Water Act (including, but not limited to, marsh, vernal pool, coastal, etc.) through direct removal, filling, hydrological interruption, or other means?

d) Interfere substantially with the movement of any native resident or migratory fish or wildlife species or with established native resident or migratory wildlife corridors, or impede the use of native wildlife nursery sites?

e) Conflict with any local policies or ordinances protecting biological resources, such as a tree preservation policy or ordinance?

f) Conflict with the provisions of an adopted Habitat Conservation Plan, Natural Community Conservation Plan, or other approved local, regional, or state habitat conservation plan?

V. CULTURAL RESOURCES -- Would the project:

a) Cause a substantial adverse change in the significance of a historical resource as defined in § 15064.5?

b) Cause a substantial adverse change in the significance of an archaeological resource pursuant to § 15064.5?

c) Directly or indirectly destroy a unique paleontological resource or site or unique geologic feature?

d) Disturb any human remains, including those interred outside of formal cemeteries?

VI. GEOLOGY AND SOILS -- Would the project:

a) Expose people or structures to potential substantial adverse effects, including the risk of loss, injury, or death involving:

i) Rupture of a known earthquake fault, as delineated on the most recent Alquist-Priolo Earthquake Fault Zoning Map issued by the State Geologist for the area or based on other substantial evidence of a known fault? Refer to Division of Mines and Geology Special Publication 42.

ii) Strong seismic ground shaking?

iii) Seismic-related ground failure, including liquefaction?

iv) Landslides?

b) Result in substantial soil erosion or the loss of topsoil?

c) Be located on a geologic unit or soil that is unstable, or that would become unstable as a result of the project, and potentially result in on- or off-site landslide, lateral spreading, subsidence, liquefaction or collapse?

d) Be located on expansive soil, as defined in Table 18-1-B of the Uniform Building Code (1994), creating substantial risks to life or property?

e) Have soils incapable of adequately supporting the use of septic tanks or alternative waste water disposal systems where sewers are not available for the disposal of waste water?

VII. GREENHOUSE GAS EMISSIONS -- Would the project:

a) Generate greenhouse gas emissions, either directly or indirectly, that may have a significant impact on the environment?

b) Conflict with any applicable plan, policy or regulation of an agency adopted for the purpose of reducing the emissions of greenhouse gases?

VIII. HAZARDS AND HAZARDOUS MATERIALS -- Would the project:

a) Create a significant hazard to the public or the environment through the routine transport, use, or disposal of hazardous materials?

b) Create a significant hazard to the public or the environment through reasonably foreseeable upset and accident conditions involving the release of hazardous materials into the environment?

c) Emit hazardous emissions or handle hazardous or acutely hazardous materials, substances, or waste within one-quarter mile of an existing or proposed school?

d) Be located on a site which is included on a list of hazardous materials sites compiled pursuant to Government Code Section 65962.5 and, as a result, would it create a significant hazard to the public or the environment?

e) For a project located within an airport land use plan or, where such a plan has not been adopted, within two miles of a public airport or public use airport, would the project result in a safety hazard for people residing or working in the project area?

f) For a project within the vicinity of a private airstrip, would the project result in a safety hazard for people residing or working in the project area?

g) Impair implementation of or physically interfere with an adopted emergency response plan or emergency evacuation plan?

h) Expose people or structures to a significant risk of loss, injury or death involving wildland fires, including where wildlands are adjacent to urbanized areas or where residences are intermixed with wildlands?

~~VIII~~IX. HYDROLOGY AND WATER QUALITY -- Would the project:

a) Violate any water quality standards or waste discharge requirements?

b) Substantially deplete groundwater supplies or interfere substantially with groundwater recharge such that there would be a net deficit in aquifer volume or a lowering of the local groundwater table level (e.g., the production rate of pre-existing nearby wells would drop to a level which would not support existing land uses or planned uses for which permits have been granted)?

c) Substantially alter the existing drainage pattern of the site or area, including through the alteration of the course of a stream or river, in a manner which would result in substantial erosion or siltation on- or off-site?

d) Substantially alter the existing drainage pattern of the site or area, including through the alteration of the course of a stream or river, or substantially increase the rate or amount of surface runoff in a manner which would result in flooding on- or off-site?

e) Create or contribute runoff water which would exceed the capacity of existing or planned stormwater drainage systems or provide substantial additional sources of polluted runoff?

f) Otherwise substantially degrade water quality?

g) Place housing within a 100-year flood hazard area as mapped on a federal Flood Hazard Boundary or Flood Insurance Rate Map or other flood hazard delineation map?

h) Place within a 100-year flood hazard area structures which would impede or redirect flood flows?

i) Expose people or structures to a significant risk of loss, injury or death involving flooding, including flooding as a result of the failure of a levee or dam?

j) Inundation by seiche, tsunami, or mudflow?

~~I~~X. LAND USE AND PLANNING - Would the project:

a) Physically divide an established community?

b) Conflict with any applicable land use plan, policy, or regulation of an agency with jurisdiction over the project (including, but not limited to the general plan, specific plan, local coastal program, or zoning ordinance) adopted for the purpose of avoiding or mitigating an environmental effect?

c) Conflict with any applicable habitat conservation plan or natural community conservation plan?

XI. MINERAL RESOURCES -- Would the project:

a) Result in the loss of availability of a known mineral resource that would be of value to the region and the residents of the state?

b) Result in the loss of availability of a locally-important mineral resource recovery site delineated on a local general plan, specific plan or other land use plan?

XII. NOISE -- Would the project result in:

a) Exposure of persons to or generation of noise levels in excess of standards established in the local general plan or noise ordinance, or applicable standards of other agencies?

b) Exposure of persons to or generation of excessive groundborne vibration or groundborne noise levels?

c) A substantial permanent increase in ambient noise levels in the project vicinity above levels existing without the project?

d) A substantial temporary or periodic increase in ambient noise levels in the project vicinity above levels existing without the project?

e) For a project located within an airport land use plan or, where such a plan has not been adopted, within two miles of a public airport or public use airport, would the project expose people residing or working in the project area to excessive noise levels?

f) For a project within the vicinity of a private airstrip, would the project expose people residing or working in the project area to excessive noise levels?

XIII. POPULATION AND HOUSING -- Would the project:

a) Induce substantial population growth in an area, either directly (for example, by proposing new homes and businesses) or indirectly (for example, through extension of roads or other infrastructure)?

b) Displace substantial numbers of existing housing, necessitating the construction of replacement housing elsewhere?

c) Displace substantial numbers of people, necessitating the construction of replacement housing elsewhere?

~~XIII~~XIV. PUBLIC SERVICES

a) Would the project result in substantial adverse physical impacts associated with the provision of new or physically altered governmental facilities, need for new or physically altered governmental facilities, the construction of which could cause significant environmental impacts, in order to maintain acceptable service ratios, response times or other performance objectives for any of the public services:

Fire protection?
Police protection?
Schools?
Parks?
Other public facilities?

~~XIV~~XV. RECREATION

a) Would the project increase the use of existing neighborhood and regional parks or other recreational facilities such that substantial physical deterioration of the facility would occur or be accelerated?

b) Does the project include recreational facilities or require the construction or expansion of recreational facilities which might have an adverse physical effect on the environment?

XVI. TRANSPORTATION/TRAFFIC -- Would the project:

a) ~~Cause an increase in traffic which is substantial in relation to the existing traffic load and capacity of the street system (i.e., result in a substantial increase in either the number of vehicle trips, the volume to capacity ratio on roads, or congestion at intersections)?~~ Exceed the capacity of the existing circulation system, based on an applicable measure of effectiveness (as designated in a general plan policy, ordinance, etc.), taking into account all relevant components of the circulation system, including but not limited to intersections, streets, highways and freeways, pedestrian and bicycle paths, and mass transit?

b) ~~Exceed, either individually or cumulatively, a~~ Conflict with an applicable congestion management program, including, but not limited to level of service standards and travel demand measures, or other standards established by the county congestion management agency for designated roads or highways?

c) Result in a change in air traffic patterns, including either an increase in traffic levels or a change in location that results in substantial safety risks?

d) Substantially increase hazards due to a design feature (e.g., sharp curves or dangerous intersections) or incompatible uses (e.g., farm equipment)?

e) Result in inadequate emergency access?

~~f) Result in inadequate parking capacity?~~

~~g~~f) Conflict with adopted policies, plans, or programs supporting alternative transportation (e.g., bus turnouts, bicycle racks)?

XVII. UTILITIES AND SERVICE SYSTEMS -- Would the project:

a) Exceed wastewater treatment requirements of the applicable Regional Water Quality Control Board?

b) Require or result in the construction of new water or wastewater treatment facilities or expansion of existing facilities, the construction of which could cause significant environmental effects?

c) Require or result in the construction of new storm water drainage facilities or expansion of existing facilities, the construction of which could cause significant environmental effects?

d) Have sufficient water supplies available to serve the project from existing entitlements and resources, or are new or expanded entitlements needed?

e) Result in a determination by the wastewater treatment provider which serves or may serve the project that it has adequate capacity to serve the project's projected demand in addition to the provider's existing commitments?

f) Be served by a landfill with sufficient permitted capacity to accommodate the project's solid waste disposal needs?

g) Comply with federal, state, and local statutes and regulations related to solid waste?

XVIII. MANDATORY FINDINGS OF SIGNIFICANCE

a) Does the project have the potential to degrade the quality of the environment, substantially reduce the habitat of a fish or wildlife species, cause a fish or wildlife population to drop below self-sustaining levels, threaten to eliminate a plant or animal community, reduce the number or restrict the range of a rare or endangered plant or animal or eliminate important examples of the major periods of California history or prehistory?

b) Does the project have impacts that are individually limited, but cumulatively considerable? ("Cumulatively considerable" means that the incremental effects of a project are considerable when viewed in connection with the effects of past projects, the effects of other current projects, and the effects of probable future projects)?

c) Does the project have environmental effects which will cause substantial adverse effects on human beings, either directly or indirectly?

ASSESSING GREEN BUILDING PERFORMANCE

A POST OCCUPANCY EVALUATION OF 12 GSA BUILDINGS

SUSTAINABILITY

The Office of Applied Science supports GSA's Public Buildings Service by generating research findings and recommending business improvements that can be directly applied to real world situations. The mission of the Public Buildings Service is to provide superior workplaces for federal customer agencies at the best value to the American taxpayer.

INTRODUCTION

SUSTAINABLE DESIGN DELIVERS

To answer the question, ‘does sustainable design deliver?’ GSA evaluated 12 sustainably designed buildings in its national portfolio. The evaluation of these buildings was comprehensive—measuring environmental performance, financial metrics, and occupant satisfaction. No previous analysis has taken such a holistic view. The buildings studied all incorporated sustainable design criteria to varying degrees, with seven receiving LEED ratings. The results of GSA's evaluation show that sustainably designed buildings outperform the national average for buildings of their type by a substantial margin.

INTEGRATED DESIGN YIELDS EVEN BETTER PERFORMANCE

The best performing buildings in the study were those that took a fully integrated approach to sustainable design—addressing site development, water savings, energy efficiency, materials selection, and indoor environmental quality. As America’s largest public real estate organization, GSA has a special responsibility to lead in building sustainably and meet federal mandates, including energy policies and Executive Orders. What the evaluation shows is that a fully integrated approach to sustainable design is helping GSA to meet its mandates by delivering buildings that use substantially less energy, cost less to operate and maintain, and lead to greater occupant satisfaction.

NEEDED NEXT: NATIONAL SUSTAINABLE BUILDING DATA

This study is an important first step in a much-needed national assessment of sustainable building performance in the public, private, and institutional sectors. GSA's evaluation establishes a new benchmark for comprehensiveness using a protocol that others can follow, both in the federal and private sectors.

RESEARCH OVERVIEW

Integration Means High Performance

"This study breaks new ground by comparing GSA's sustainably designed buildings against US commercial buildings, using the latest performance data. Its findings will be relevant to building owners and developers, public and private, across the country."

-DAVID WINSTEAD
Commissioner, Public Buildings Service

The US General Services Administration (GSA) commissioned a comprehensive post-occupancy evaluation of 12 of its sustainably designed buildings.[1] The measures studied included environmental performance, financial metrics, and occupant satisfaction. No previous US study has taken such a holistic approach to building performance. The LEED buildings evaluated represented one-third of the total LEED buildings in GSA's national portfolio at the time the study was conducted.

The study compared the energy performance, operating cost, and water use of the 12 GSA buildings against the average performance of US commercial buildings, using the following sources of data:

Measurement	Data Source[2]
EUI	CBECS National Survey of Commercial Buildings constructed between 1990 and 2003[3]
CO_2	ENERGY STAR[4]
Maintenance Costs:	IFMA[5] and BOMA[6] 2006/2007 Surveys reporting 2003-2005 data
Water Use:	Federal Water Use Index[7]
Occupant Satisfaction:	Center for the Built Environment, UC Berkeley[8]

The study found that GSA's green buildings outperform national averages in all measured performance areas—energy, operating costs, water use, occupant satisfaction, and carbon emissions. The study also found that GSA's LEED Gold buildings, which reflect a fully integrated approach to sustainable design—addressing environmental, financial, and occupant satisfaction issues in aggregate—achieve the best overall performance.

KEY FINDINGS:

Compared to national averages, buildings in this study have:

26%
Less energy use
(65 kBtu/sf/yr vs. 88 kBtu/sf/yr).

13%
Lower aggregate maintenance costs ($2.88/sf vs. $3.30/sf)

27%
Higher occupant satisfaction

33%
Fewer CO_2 emissions
(19lbs/sf/yr vs. 29lbs/sf/yr)

RESEARCH CONTEXT

A Comprehensive Evaluation

"We believe that 'green' building and sustainable design and operation has a very positive impact on the people that work in our buildings, in terms of their morale and productivity. 'Green' building is the right thing to do, and it's also the right business thing to do."

DAVID BIBB
Acting Administrator, GSA

GSA asked Pacific Northwest National Laboratory (PNNL) to evaluate 12 of GSA's sustainably designed buildings, and answer this question:

While sustainably designed buildings promise higher performance, do they deliver?

The study evaluated actual, not modeled, building performance, so the results are reliable and objective. Successes and shortcomings were identified, along with areas requiring further research, to provide best practices to emulate and actions to take to improve performance.

The 12 buildings selected reflect different US regional climates, a mix of uses (courthouses and offices), and a mix of build-to-suit leases and federally owned buildings. Land ports of entry were excluded because, as a building type, they are too different to allow meaningful comparisons. Eight of these buildings were designed to meet or exceed basic LEED certification. The other four were designed to meet the requirements of other programs, including ENERGY STAR and the California Title 24 energy standard.

The research team used a consistent evaluation process for every building studied:

- Obtaining and reviewing one year of operating data
- Surveying building occupants
- Interviewing the building manager
- Conducting an expert walkthrough

To make the study useful to a larger audience, the team compared each performance measure with the national average for US commercial buildings. The latest available benchmark data comes from widely accepted industry and government standards.

ABOUT THE LEED GREEN BUILDING RATING SYSTEM

The US Green Building Council's (USGBC) Leadership in Energy and Environmental Design (LEED) Rating System is a nationally accepted third party certification program for green building design, construction, and operation. As the USGBC puts it, "LEED promotes a whole-building approach to sustainability by recognizing performance in five key areas: sustainable site development, water savings, energy efficiency, materials selection, and indoor environmental quality." LEED closely approximates GSA's holistic approach to sustainable building development and operation.

The LEED Rating System addresses new construction and renovation, operations and maintenance of existing buildings, design of commercial interiors, building core and shell development, as well as neighborhood development and homes.

LEED provides four measures of performance: basic certification, Silver, Gold, and Platinum, based on a set of prerequisites and credits in the five major categories listed above. Each measure represents an incremental step toward integrating the different components of sustainable design, construction, and operation to achieve optimal performance.

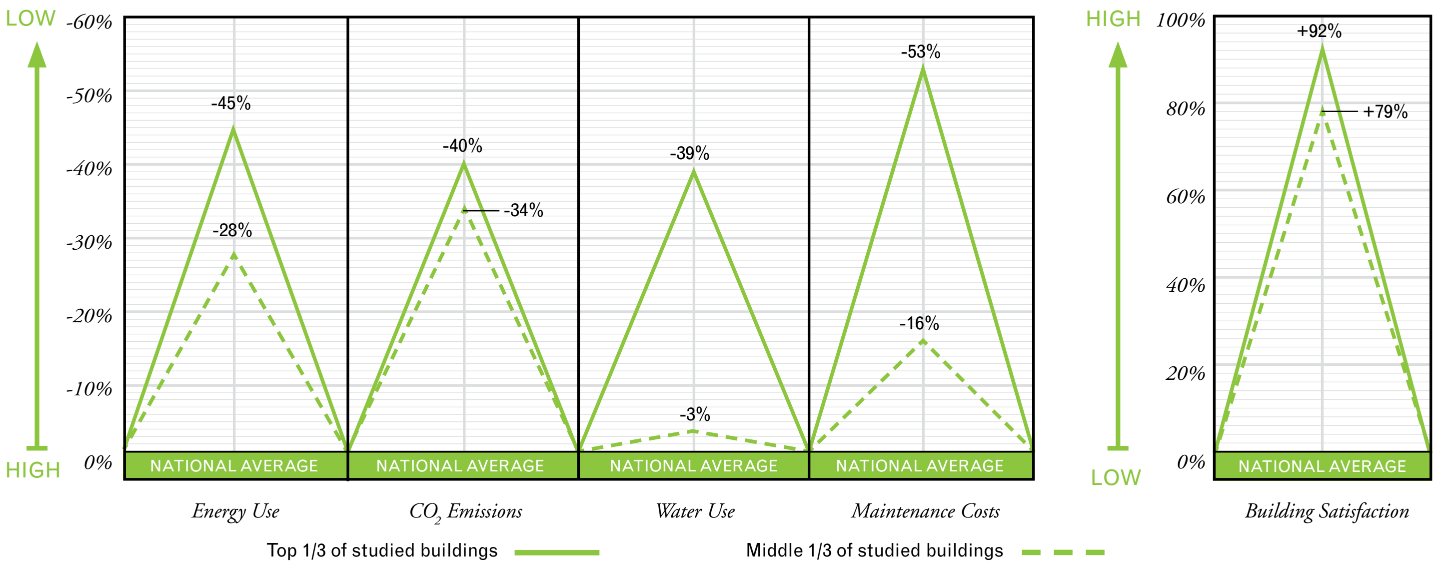
HOW THE GSA STUDY BUILDINGS PERFORM

Figure 2: Comparison Against National Averages



THE TOP PERFORMING BUILDINGS IN EACH METRIC DELIVER SIGNIFICANTLY BETTER RESULTS THAN THE NATIONAL AVERAGE.

GSA STUDY BUILDINGS: FAST FACTS

Year Built: 1910
Year Renov: 2005
Employees: 105
Energy Star: 82
CO_2e: 2,440 mt
LEED-NC Certified

CLEVELAND

The Metzenbaum Courthouse is on the National Register of Historic Places. The renovations preserved 96% of the existing shell and 59% of the interior elements.

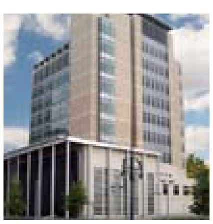
The courthouse won GSA's Environmental Award for recycling because of its seven-material collection system and green housekeeping practices.

Year Built: 1933
Year Renov: 2005
Employees: 45
Energy Star: 78
CO_2e: 945 mt
LEED Registered

DAVENPORT

The Davenport Courthouse is on the National Register of Historic Places. The renovation maintained the integrity of the historic space, while updating the mechanical systems in the building.

The courtrooms incorporate techniques to bring in daylight and the mechanical systems use variable speed drives. The HVAC system consists of water-cooled chillers, boilers, and air handling units.

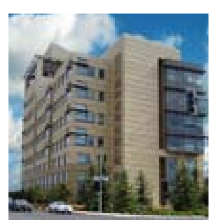


Year Built: 2002
Employees: 170
Energy Star: 77
CO_2e: 4,668 mt

DENVER

The Arraj Courthouse was designed as a green courthouse prior to the completion of the LEED rating system. It is currently seeking LEED for Existing Buildings Certification.

Denver employs a hybrid underfloor air distribution system, HVAC and lighting sensors, as well as photovoltaic panels.



Year Built: 2001
Employees: 85
Energy Star: 92
CO_2e: 2,666 mt
CA Energy Standard Title 24

FRESNO

The Coyle Courthouse and Federal Building houses 14 courtrooms and is the tallest building in the city (11 floors high).

Designed under California's Title 24 energy standard, the building includes high efficiency lighting, underfloor air distribution systems, water-cooled chillers, and natural gas boilers.

Year Built: 2001
Employees: 85
Energy Star: 87
CO_2e: 1,397 mt

GREENEVILLE

The Quillen Courthouse replaced a smaller courthouse from which the occupants reclaimed quality historic furniture.

Some of the energy-efficiency features include a well-insulated white roof and an Energy Management Control System of lighting and occupancy sensors. It also scores the highest occupant satisfaction for air quality, acoustics, and lighting.

Year Built: 1986
Year Renov: 2005
Employees: 285
Energy Star: 91
CO_2e: 1,516 mt
LEED-EB Silver

KNOXVILLE

Located in downtown Knoxville, the Duncan Federal Building currently houses a range of services including the FBI, US Customs, and HUD.

Alterations to the building incorporate high-efficiency lighting, enhanced metering techniques, and low-flow fixtures. The roof design reduces the heat island effect, as well as housing photovoltaic panels.

Year Built: 2001
Employees: 252
Energy Star: 80
CO_2e: 2,150 mt
LEED-NC Silver

LAKEWOOD

The facility at Lakewood for the Department of Transportation is a LEED Silver-leased building.

Some features include low-emitting material selection, and daylight and views in 91% of regularly occupied spaces. In addition, all building occupants receive a booklet about the design and operations of the building.

Year Built: 2001
Employees: 252
Energy Star: 79
CO_2e: 1,161 mt
LEED-NC Silver

OGDEN

Renovations transformed the historic Scowcroft Federal Building into usable office space meeting the IRS's specific needs.

The space incorporates earthquake prevention upgrades, improved roof insulation, radiant baseboard heating, and an underfloor air distribution system coupled with indirect/direct evaporative cooling.

Year Built: 2001
Employees: 252
Energy Star: 85
CO_2e: 1,168 mt
LEED-NC Gold

OMAHA DHS

The Omaha Department of Homeland Security was designed to house multiple DHS agencies, and recently won the 2007 American Council of Engineering Award for its design.

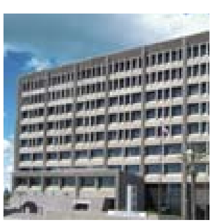
As a LEED Gold building, the facility incorporates daylight and rainwater-harvesting systems, a ground source heat pump, and Green Seal janitorial products.

Year built: 2004
Employees: 125
Energy Star: 86
CO_2e: 872 mt
LEED-NC Gold

OMAHA NPS

The Curtis National Park Service building was built on a brownfield as part of an urban redevelopment effort.

The building showcases passive solar design, daylight harvesting and HVAC sensors, as well as underfloor air distribution. Use of native and adaptive vegetation eliminated the need for irrigation. Operations also include green housekeeping practices.

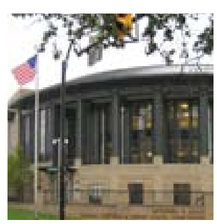


Year Built: 1975
Year Renov: 2005
Employees: 409
Energy Star: 92
CO_2e: 1,344 mt
CA Energy Standard Title 24

SANTA ANA

Renovated in 2005, the Santa Ana Federal Building lies in the heart of the civic center district and accommodates a large flow of visitors to the building each day.

This building features high-efficiency lighting and HVAC systems, a new roof, energy-efficient elevators, and lighting sensors.



Year Built: 2002
Employees: 45
Energy Star: 58
CO_2e: 655 mt
LEED-NC Certified

YOUNGSTOWN

The Jones Federal Building and Courthouse facility was built on a brownfield, and was part of the city's urban revitalization.

Youngstown incorporates building controls and daylighting to over 75% of occupied spaces. Unique features include a storm water management demonstration, a white membrane roof, and light-colored pavement.

FINDING 1:

Fully Integrated Design Delivers Higher Performance

GSA's sustainably designed green buildings have 26% lower energy use compared to the National Average.

(65 kBTu/sf/yr vs. 88 kBtu/sf/yr)
Source of National Average: CBECS

To achieve LEED Gold certification, credits must be obtained in all five rating areas, requiring a completely integrated approach to sustainable building design. The two LEED Gold buildings in this study clearly show that a comprehensive approach yields broad, holistic performance benefits. While neither building led in every category, these two buildings were the only ones studied that achieved consistently high levels of performance on all measures.

The **Curtis National Park Service (NPS) building,** Omaha, Nebraska, performed well in all categories. Its ENERGY STAR rating (86) is in the top third for the group. Its water costs are 91% below the BOMA/IFMA baseline. Its domestic water use is 50% below baseline. Its CO_2 emissions are 34% under baseline, putting it in the top half. Its emissions from occupants' commutes, 1.7 metric tons per person, put it in the top one-third.

The **Omaha Department of Homeland Security (DHS) building,** Omaha, Nebraska, performed well across all categories. Its ENERGY STAR rating (85) is also in the top third for the group. Its water costs are 66% below the BOMA/IFMA baseline, achieved using rainwater harvesting and low-flow and auto-flow lavatory fixtures to offset its greater public use. DHS has 65 regular occupants and 360 occupant visitors while NPS has 125 regular occupants and 134 occupant visitors. DHS's domestic water use is 58% below baseline.

LESSON LEARNED

Across all buildings studied, building performance tracks design intent. Buildings designed with a strong energy focus—compliance with California's demanding Title 24 energy code or ENERGY STAR—had outstanding energy performance, although with a lesser achievement in terms of water use intensity. One LEED certified building did not pursue energy efficiency during design. As a result, it achieved no LEED energy optimization credits, and had the lowest ENERGY STAR rating in the study.

NATIONAL BUILDING FACTS

31%
projected increase in energy consumption by the year 2030 despite dramatic gains in energy efficiency.[9]

20%
of U.S. drinking water supply is consumed by commercial buildings.[10]

2 trillion
gallons of water a year would be saved if commercial buildings reduced their water consumption by 10%.[11]

Figure 3: Top Performers by CO_2 Emissions (lbs/sf/yr)

Source of National Average: Energy Star

ALL BUILDINGS IN THIS STUDY PRODUCE A SMALLER CARBON FOOTPRINT THAN THE NATIONAL AVERAGE.

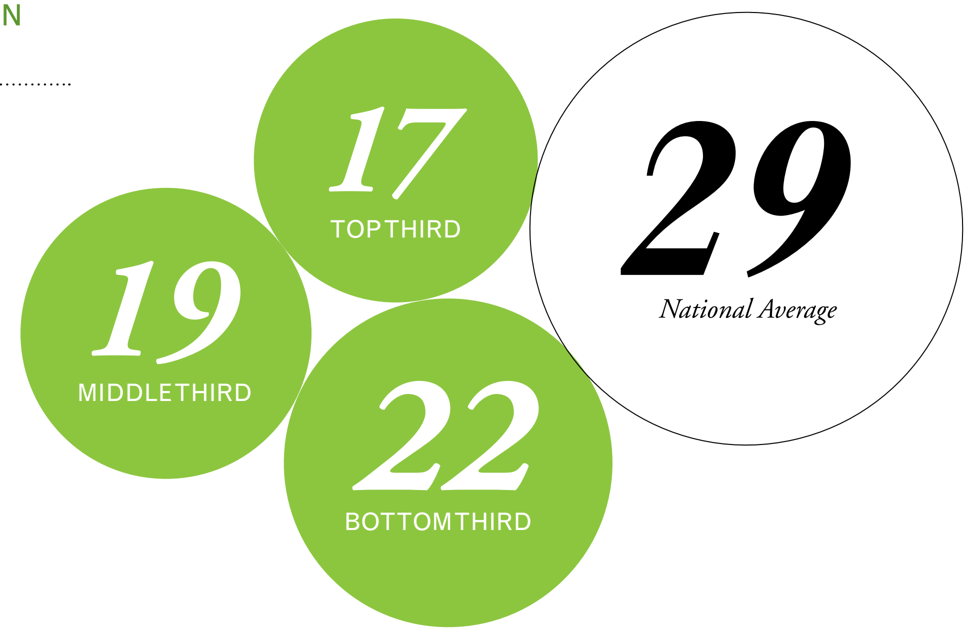


Figure 4: Top Performers by Water Use (thousand gallons/yr)

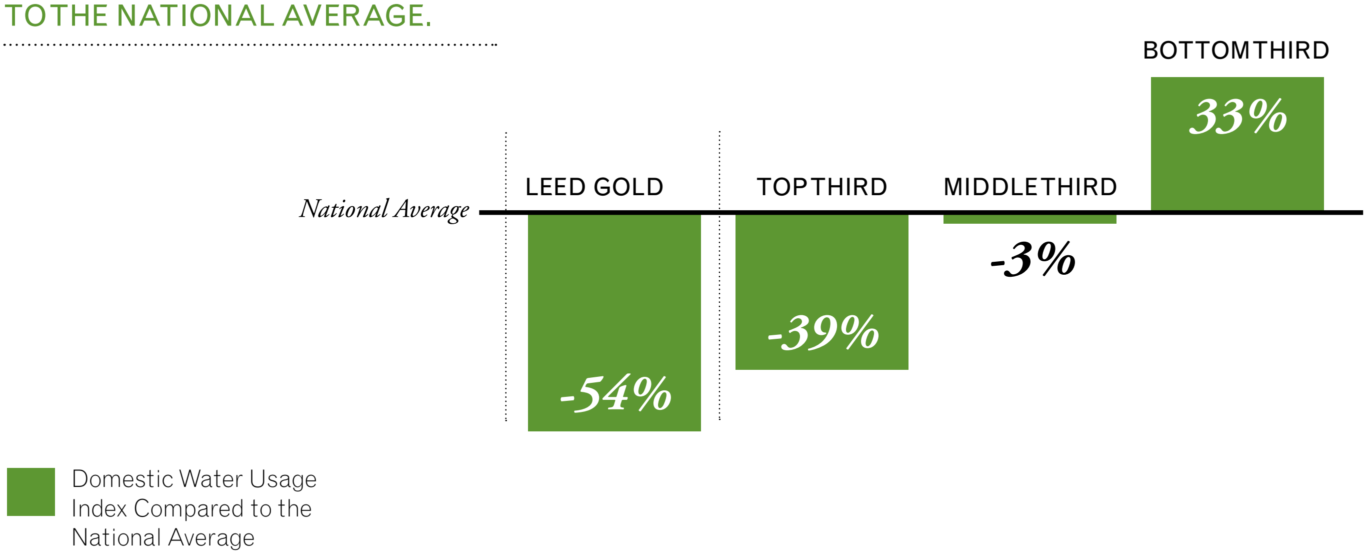
Source of National Average: Federal Water Use Index

LEED GOLD BUILDINGS IN THIS STUDY HAVE SIGNIFICANTLY LOWER WATER USE COMPARED TO THE NATIONAL AVERAGE.



FINDING 2:
GSA's Green Buildings Cost Less to Operate

The five top-performing buildings studied spent 14% to 45% less on energy than the National Average.

Source of National Average: BOMA/IFMA

Why do operations and maintenance (O&M) costs matter? Considered in aggregate, they approximate the consumption side of overall sustainable performance. As a group, the 12 buildings studied performed only slightly better than the national average for US commercial buildings: 7% below that baseline. However, the top-performing one-third of the group did much better, at 41% below.

The two LEED Gold buildings were among the best performers from an O&M cost perspective. Lower utility and janitorial costs and savings from recycling resulted in top scores for the Curtis National Park Service building and the Omaha Department of Homeland Security building. The use of green cleaning practices enhanced their performance.

On average, the bottom quartile of the buildings studied had considerably higher costs than the industry baseline: 45% above the national average for US commercial buildings. These buildings had unusually high maintenance costs and, in one case, an operating emergency.

LESSON LEARNED

The best practice lesson here is that O&M costs are lowest when sustainability is integral to every aspect of a building, including cleaning and recycling. Building and systems efficiency alone isn't enough. Upfront investments in sustainable measures need to be matched by sustainable O&M practices.

NATIONAL BUILDING FACTS

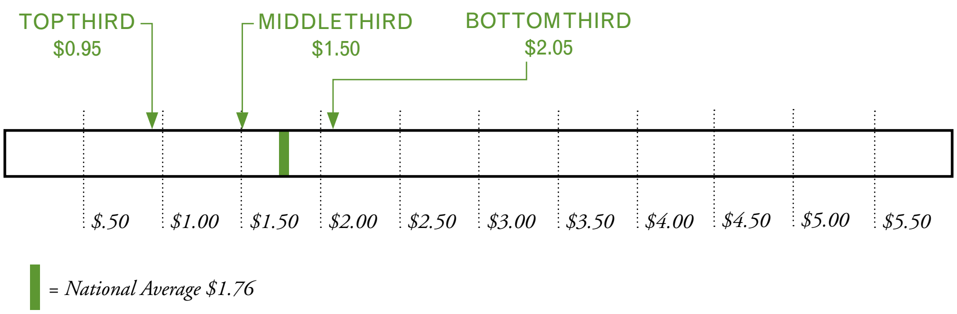
18%
of total U.S. energy use consumption comes from commercial buildings.[12]

Why water efficiency?
Between 1950 and 2000, the US population nearly doubled. In that same period, however, public demand for water nearly tripled. Americans now use an average of 100 gallons of water per day—enough to fill 1,600 drinking glasses![13]

Figure 5: Top Performers by Energy Cost ($/sf/yr)

Source of National Average: BOMA/IFMA

THE TOP-PERFORMING SUSTAINABLE BUILDINGS STUDIED SHOWED CONSISTENTLY LOWER ENERGY COSTS THAN NATIONAL AVERAGES.



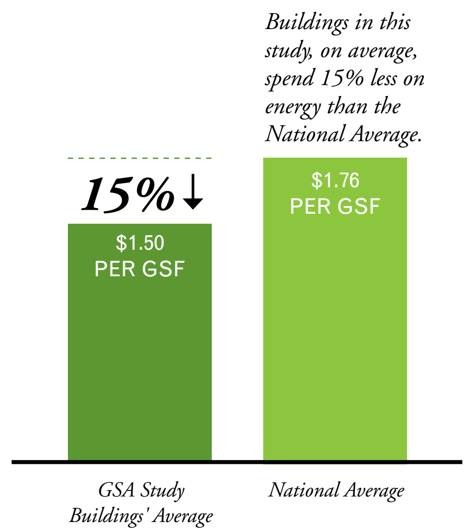


Figure 6: Top Performers by Aggregate Maintenance Cost ($/sf)

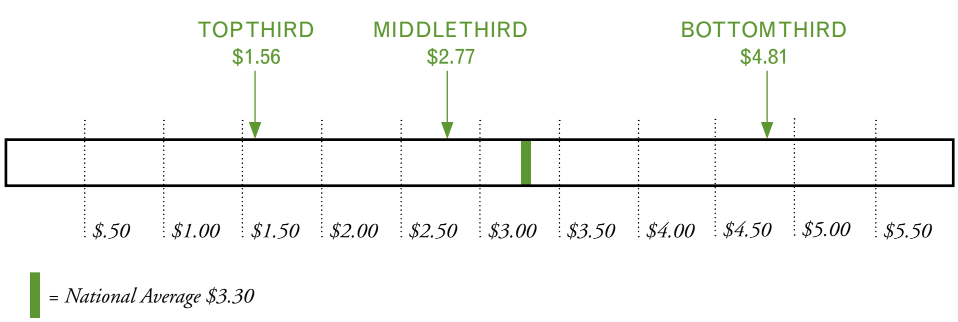
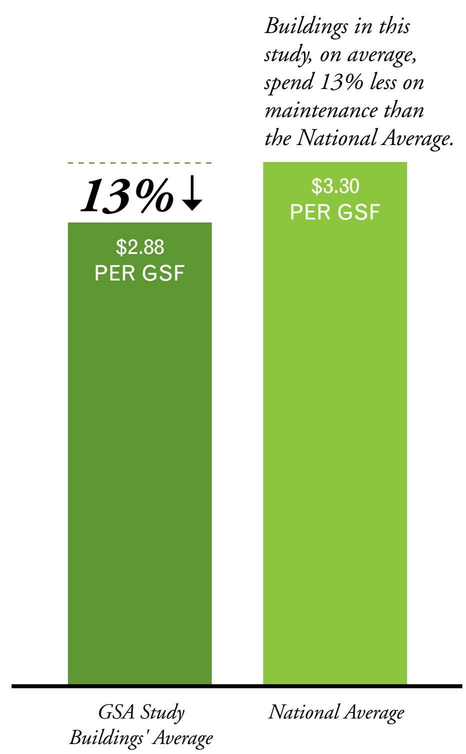
Source of National Average: BOMA/IFMA

THE TOP-PERFORMING SUSTAINABLE BUILDINGS STUDIED SHOWED CONSISTENTLY LOWER AGGREGATE MAINTENANCE COSTS THAN THE NATIONAL AVERAGE.





FINDING 3:

GSA's Green Buildings have Satisfied Occupants

GSA's sustainably designed green buildings demonstrate a 27% higher occupant satisfaction than the National Average.

Source for National Average: CBE, UC Berkeley[14]

This study provides important new evidence that occupant satisfaction is higher in sustainably designed buildings. Occupant satisfaction is important because it correlates with personal and team performance. That often means higher productivity and creativity for an organization.

As a group, the 12 sustainable buildings studied scored better in occupant satisfaction than the national average for US commercial buildings. Half of the buildings studied scored in the top quartile for occupant satisfaction. Significantly, their average scores in all categories were higher than those of LEED certified buildings in the private sector[14]. This suggests that GSA's integrated life cycle approach will be a valuable model for public and private organizations.

For the lower-performing buildings, the study found that occupant satisfaction is undermined by poor acoustics, lighting and maintenance problems. A low level of ambient noise, a lack of sound masking, and a perceived lack of privacy make acoustic quality worse. The poorly calibrated systems that turn lights on and off in response to daylight conditions may cause problems for some occupants. Mechanical failures and poor maintenance can drive down satisfaction scores.

LESSON LEARNED

GSA's sustainably designed buildings are scoring points with their occupants in terms of overall building and workplace quality, indoor air quality, cleanliness, and quality of maintenance. We also gained the following insights from the lower-performing buildings:

First, acoustic performance matters, and should be addressed by appropriate teaming and design criteria at the outset of every project.

Second, both change management and periodic fine-tuning may be needed to make automated systems work well for building occupants, at least until these systems are fully accepted.

Third, good building maintenance is a foundation stone of occupant satisfaction. Don't neglect it.

NATIONAL BUILDING FACTS

79%
of employees surveyed were willing to forgo income to work for a firm with a credible sustainable strategy.[15]

80%
of employees surveyed said they felt greater motivation and loyalty toward their company due to its sustainability initiatives.[16]

OCCUPANT SATISFACTION SURVEY

Figure 7: Comparison Against National Averages

FINDING 4:

Green Buildings Deliver on GSA's Mandates

New executive and legislative mandates raise the performance requirements for buildings in GSA's national real estate portfolio. (See chart to right)

To meet these new requirements, GSA will need to ensure that its future buildings, including both new construction and major renovation projects, achieve a consistently high standard of performance. The study found a strong positive correlation in that direction. Taken as a group, these 12 sustainably designed buildings use less energy and water, and have a smaller carbon footprint than the national average for US commercial buildings.

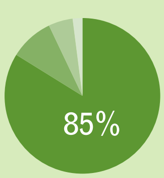
LESSON LEARNED

Although they were not designed to meet GSA's new legislative mandates, the top performing quartile of the buildings studied already meet 2015 requirements for reducing metered energy and water use. GSA can build on this strong foundation of achievable performance. GSA is and will continue to be an important benchmark for other public agencies and for companies and institutions as they plan and implement their building programs.

MANDATE	PERFORMANCE REQUIREMENT
EPAct 2005	• Modeled energy performance must be at least 30% better than ASHRAE 90.1-2004 by 2015
EO 13423	For entire GSA portfolio: • 3% per year metered energy use reduction • 30% metered energy use reduction by 2015 (an average of 54.6 kBtu per sf per year) • 16% metered water use reduction by 2015
EISA 2007	For new GSA buildings and major renovations, reduce fossil fuel generated energy consumption by: • 55% by 2010 • 100% by 2030

For additional information on EISA, EPAct 2005, and EO 13423:
www.wbdg.org/references/federal_mandates

NATIONAL BUILDING FACTS



CO_2 EMISSIONS

In the year 2004, the United States emitted over 7 billion metric tons of greenhouse gases. Carbon dioxide accounted for the largest percentage of greenhouse gases **(83%),** followed by methane **(9%),** nitrous oxide **(5%),** and high global warming potential gases **(2%).**[17]

GSA ON THE GROUND

Green Elements of the Omaha Department of Homeland Security

Although designed in 2004, the Omaha Department of Homeland Security already meets the latest federal mandates.

Landscaping captures storm water run-off

Bike racks encourage people to leave their cars behind

The building features access to windows and daylight

Skylights provide daylight where needed

Rainwater is stored and reused for landscape irrigation

A ground source heat pump reduces energy costs

TEST YOUR KNOWLEDGE:

QUESTION 1
How much of US total energy is used by commercial buildings?

QUESTION 2
How much of US energy is generated by coal?

QUESTION 3
How much of US electricity is used by commercial buildings?

QUESTION 4
Over the 30 year life-cycle cost of an office building, what percentage is dedicated to occupant salaries?

QUESTION 5
How much time does the average human spend indoors?

QUESTION 6
Compared to average US buildings, what is the aggregate reduction in energy use over the past year for the 12 buildings studied?

QUESTION 7
Compared to average US buildings, what is the aggregate reduction in domestic water use over the past year for the 12 buildings studied?

QUESTION 8
Compared to average US buildings, what is the aggregate reduction in carbon emissions over the past year for the 12 buildings studied?

QUESTION 9
Compared to average US buildings, how much did the 12 buildings studied save in aggregate maintenance costs over the past year?

ANSWERS

1. 18%
2. 49%
3. 35%
4. 88%
5. 90%
6. 616,000 BTUs
7. 313,000 gallons
8. 172,000 mt, equivalent to the annual emissions for 28,667 cars.
9. $1,175,707

LESSONS LEARNED FROM CASE STUDIES OF SIX HIGH-PERFORMANCE BUILDINGS
National Renewable Energy Laboratory
2006

Analyzed the design, construction, and energy performance of six commercial buildings. All of the low-energy buildings used more energy than predicted, but those designed with a whole building approach and with the “strongest” energy goals had the best energy performance. Monitoring buildings to provide feedback improves their energy performance.

THE ENERGY CHALLENGE: A NEW AGENDA FOR CORPORATE REAL ESTATE
Rocky Mountain Institute / CoreNet
2007

Buildings use two-fifths of the world’s materials and energy and one-sixth of its fresh water. In the US, buildings make up 85% of all fixed US capital assets. In short, buildings are part of the problem and part of the solution. The Energy Challenge identifies barriers, documents successes, and recommends actions to achieve greater energy efficiency in US corporate real estate.

THE COST OF GREEN REVISITED
Davis Langdon
2007

Found no significant difference in the average costs between green and other buildings. The study also found that the construction industry has embraced sustainable design in most US regions, and no longer views sustainable design measures as an extra cost burden.

ENERGY PERFORMANCE OF LEED NC BUILDINGS
New Buildings Institute
2008

Compares design intent to energy performance in 121 LEED-rated buildings. Office buildings used 33% less energy and all buildings used 24% less energy than the CBECS average for US commercial buildings. Nearly half the buildings had an ENERGY STAR rating of at least 75; the average rating for all buildings was 68, with a quarter rated below 50.

GLOSSARY

BOMA
Building Owners and Managers Association International. This study used their research to obtain the national average for maintenance costs.

CBE
Center for the Built Environment. This study used their research as a basis for the occupant satisfaction surveys, as well as obtaining the national average for general building satisfaction, cleanliness, lighting, air quality, acoustic, and thermal satisfaction.

CALIFORNIA TITLE 24 ENERGY STANDARD
A California-specific building standard that compiles codes from three sources: standards from national model codes, adapted national model codes to meet California conditions, and new standards to address particular California concerns.

CBECS
Commercial Buildings Energy Consumption Survey. The survey gathers and compiles energy use and cost information for US commercial buildings. This study used their research to obtain the national average for energy use.

CH
Courthouse

ENERGY STAR
Energy Star is a rating to promote energy efficiency in products and buildings. This study used their research to obtain the national average for CO_2 emissions. It is a joint program between the US Environmental Protection Agency and the U.S. Department of Energy.

EUI
Energy Use Intensity.

FB
Federal Building

Federal Water Use Index
This study used the Department of Energy's research to obtain the national average for water use.

GSF
Gross square feet. Refers to a building's overall floor plate size, measuring from the outside of its exterior walls and including all vertical penetrations, such as walls and elevator shafts.

IFMA
International Facility Management Association. This study used their research to obtain the national average for energy costs.

kBtu
1000 British thermal units

mt
Metric ton

EXECUTIVE SUMMARY

The phase out of CFCs and HCFCs under the Montreal Protocol requires the selection of replacement technologies, and in many cases are these alternative fluids. These technologies have differing impacts on global climate change, health, safety and other environmental endpoints, and different private and social costs. Analyses that focus on one or more of these types of impacts can help decision-makers to make choices about competing replacement technologies. However the outcomes of such analyses are influenced by many factors not intrinsic to the technologies. Examples of these are the analytical approach (e.g., top-down compared with bottom-up), the degree of product or process optimization, service and disposal practices, regional circumstances and a wealth of other inputs and assumptions. Therefore in order to make informed choices, decision-makers need to be aware of the sensitivities, uncertainties and limitations inherent in each type of analysis, and must be able to evaluate whether the approach and assumptions used in an analysis are reasonable for the regions and time periods in which the competing technologies are to be applied.

The purpose of this chapter is to provide an overview of the different types of analyses as well as concise guidance on how to evaluate and apply these. For each type of analysis, the most important analytical approaches and variables are discussed, along with the associated sensitivities, uncertainties and limitations. The requirements and limitations of each method are explained. This provides a point of reference for the selection of assessment methods in the technical chapters of this report and gives a framework which helps to harmonize the reporting of results. Further the chapter provides an introduction to the technical chapters and to their subsequent application, non-application and specific-default macrodata. A description of the key methods used in these chapters is also given.

An overview is given of the key approaches used to compare the lifetime, and the direct and indirect emissions of different types of systems. These range from the modelling of partial or complete systems to measured values of individual systems or of representative equipment populations. There can be significant differences between the results from different approaches and therefore relevant policy comparisons can only be made if there is maximum transparency and a harmonization of assumptions. Reference values for emissions from energy consumption in the production of fluids and products are given along with values for CO_2 emissions from electricity generation for the national electricity grids. These values differ significantly over time and between regions, suggesting that great care should be taken if results of system comparisons based on total equivalent warming impact (TEWI) or Life Cycle Assessment (LCA) are transferred to related applications or other regions.

In any economic analysis, the cost of mitigation is calculated as the difference in costs (defined in monetary units) between a reference situation and a new one characterized by lower emissions. Both situations should, as far as possible, be defined such that the assessment can include all major economic and social impacts of the policies and the resulting impact on greenhouse-gas emissions. At the project level, the simplest cost assessment using cost-benefit analysis considers that a new technology requires capital investment to cover costs accounted in the project. Major categories of costs accounted in a project are labour, land, material, energy, investments, environmental services and foreign exchange. These costs are known as the direct engineering and financial costs. A more complete cost evaluation requires the inclusion of externalities, the costs not paid directly by the private commercial entity developing the project. External costs are paid by society and where available, these should be considered for wider policy assessments. In principle, the total cost to society (*social cost*) consists of both the *external cost* and the *private cost*. For the assessment of engineering-type measures relevant to this report, the focus is best placed on private costs, expressed in terms of their net present value (NPV) or as levelized costs to account for the time distribution of costs and investments during the project lifetime.

Health and safety issues are an integral aspect of decisions concerning the choice of fluids. These decisions can have far-reaching consequences for the workforce, the population, industry, the environment and the economy. The prevention of negative health and safety impacts requires methodologies such as risk assessment, risk management, and policy and regulatory controls. Health and safety issues are considered under the following criteria: Flammability, acute toxicity, chronic toxicity, carcinogenicity, acute ecotoxicity, chronic ecotoxicity, and persistence. Information on the substances covered by this report was drawn from several sources. The technical chapters provide detailed information on the substances and the products these are used in is provided in the subsequent technical chapters. The information is divided into general characteristics of a group of fluids followed by typical characteristics of certain fluids within the group. There are significant differences between the various fluid groups, and in some cases within the fluid groups, with respect to flammability, acute toxicity, ecotoxicity and persistence. The design of systems and processes should reflect the specific weaknesses of the fluids used.

A fairly wide range of assessment methods is described so that the impacts of different technologies on the environment and climate can be compared and understood. One significant problem identified is that methodologies like LCA and TEWI are installation-specific and therefore do not provide meaningful results for entire sectors. It is also demonstrated that the available assessment methodologies are not generic but have been developed for a specific purpose. Each of the methodologies can play a role in technology choices if used appropriately.

The use of fluorocarbons is specific to certain technical sectors. In these sectors, technology selection and product development are influenced by the customers and a number of other factors, such as the enforcement of legislation, of a local, national or regional nature. An overview of the regional factors that should be reflected in the inputs for analyses is given. These factors include climate, labour costs, the availability of capital, skilled labour and spare parts, the replacement rates of

systems, and disposal pathways. In this section a regional partitioning of developed and developing countries is used according to the Montreal Protocol.

For applications involving banked amounts of fluids, an overview is given of the available approaches and associated uncertainties for the modelling of process emissions compared to emissions in the usage phase and upon disposal. For both areas, the future usage pattern and emissions can be estimated using bottom-up and top-down approaches. The former ideally involves the modelling of the emissions of individual substances or substance classes from populations of equipment. The properties of these pieces of equipment will often be modelled differently for different years and in different regions so as to reflect anticipated technological changes. In contrast to these technology-rich approaches, top-down models rely on historically established relations between sales into certain sectors and economic growth. This approach is typically weakest in capturing long-term technological changes but is good for the appropriate capture of mid- to long-term growth and wealth effects. However for technologies involving the use of fluorinated greenhouse gases, uncertainties associated with both bottom-up and top-down models become so significant that projections beyond the year 2020 are unreliable.

In the past, too little attention was paid to ensuring the comparability and transferability of results from different technology assessments. The treatment of uncertainties is often incomplete and therefore the resulting recommendations are often not robust enough to be transferred across a sector. To address these concerns, analysts and decision-makers should ensure, wherever possible, that the assumptions and methods used to compare competing technologies are consistent and that uncertainties and sensitivities are identified and quantified. The development of simple and pragmatic standard methodologies and the respective quality criteria should be continued. It is recommended that future efforts should focus on increasing the involvement of relevant stakeholders and introducing additional measures to increase transparency for outside users, for example by providing more extensive documentation. For certain regions and policy questions the amount of resources needed for some of the assessment methods is prohibitive. There is a need for simple and pragmatic assessment methods that can also be used in regions with very limited resources.

3.1 Introduction

This chapter provides public and corporate decision-makers with an overview of assessment methodologies that can be used to support informed decisions on technologies to replace the use of ozone-depleting substances (ODSs). Such decisions are taken in the context of the phase out of ozone-depleting substances under the Montreal Protocol, and national and international policies aimed at reducing emissions of anthropogenic greenhouse gases. The latter include not only direct emissions of fluids during production, use and disposal but also energy-related emissions over the lifetime of products and equipment. Decisions on technology choices and the definition of appropriate practices will often take place at the level of individual projects but could also be important in designing policies. This chapter has therefore been designed as a toolbox for decision-makers. The intention is to give an overview of the most common assessment methodologies for evaluating competing technologies, including a description of how these are applied and their practical limitations. It also provides information used by several subsequent chapters in this report.

Fluorinated substances such as hydrofluorocarbons (HFCs) and perfluorocarbons (PFCs) are being widely used or are being considered for future use as refrigerants, blowing agents in foam production, propellants for aerosol applications, solvents, surfactants, fire-fighting agents and anaesthetics. These substances are used in many technical applications over a wide range of conditions. They are replacing the use of CFCs and HCFCs, which were and are being banned due to their significant impact as ODSs. In quantitative terms, stationary refrigeration and air conditioning, mobile air conditioning and foam blowing dominate usage and emissions in most countries.

As these substances are potent greenhouse gases, considerable efforts are underway to reduce the emissions of these from products or processes to well below the levels that can be obtained on the basis of current technical and economic drivers. The principal available emission reduction options – over the lifetime of the product equipment – for the aforementioned applications fall into five main groups:

a) Improved containment of fluorinated gases during the life cycle of a product or system (manufacture, use and decommissioning/disposal);
b) Use of technologies with a lower fluid charge;
c) Use of alternative fluids with a zero/low global-warming potential (GWP);
d) Use of not-in-kind (NIK) technologies;
e) Process modifications to avoid byproduct formation or emission.

The benefits of reducing emissions of fluorinated gases clearly need to be offset against potential changes in terms of energy efficiency, safety and costs or the impact on environmental categories such as air quality and the continuation of damage to the ozone layer (see Figure 3.1). The specific details of a sector – or even the application concerned – need to be taken into account when making decisions about technological options.

As a result of international concerted action, many of the sectors and applications covered in this report have undergone a rapid transition away from the use of ODSs. This mandated transition has also led to a significant increase in knowledge about technological alternatives to the use of ODSs and has resulted in increased innovation. This high rate of innovation has made it more difficult to appropriately characterize technology options and then to assess them in terms of their performance or costs. Therefore it is now more important than ever to apply consistent methodologies, as outlined in this chapter, for the purpose of producing valid comparisons upon which robust technology choices can be based.

The subsequent sections of this chapter cover the following aspects of technology assessment relevant to the sectors using fluorinated gases: Key performance characteristics such as direct and indirect emissions (3.2), categories of costs (3.3), consideration of health and safety issues (3.4), assessment of climate and environmental impacts (3.5), regional dimensions of technology choices (3.6), basics of emission projections (3.7) and future methodological developments (3.8).

3.2 Direct and indirect emissions

This section considers aspects related to emissions from products and equipment using HFCs or PFCs. Direct and indirect emissions need to be identified to account for the full inventory of such emissions. Indirect emissions are usually associated with the amount of energy consumed for the operation of equipment loaded with the fluid. Table 3.1 gives an overview of the relative contribution of direct HFC emissions to the total greenhouse-gas emissions associated with systems, for example, a domestic refrigerator, a refrigerated truck, a supermarket cooling system or the energy losses through an insulated area of building surface. The table shows that for several important technical systems (e.g. mobile air conditioners or supermarket refrigeration) direct and indirect emissions are of the same order of magnitude but that for several other applications, energy-related indirect emissions outweigh direct emissions by one or two orders of magnitude. The methodologies stated in Table 3.1 are described in greater detail in Section 3.5. Specific values are highly dependent on emission factors, end-of-life treatment of equipment, the GWP of the fluids used and the carbon intensity of the energy supply system.

3.2.1 Direct emissions

Emissions are possible throughout the lifetime of the fluid, from the initiation of fluid manufacture through use within the intended equipment, to its destruction. The following paragraphs describe key stages within the lifetime of the fluid where direct emissions occur. The identification of emissions from these various stages is necessary for both the environmental impact and safety assessments of applications that use any type of fluid.

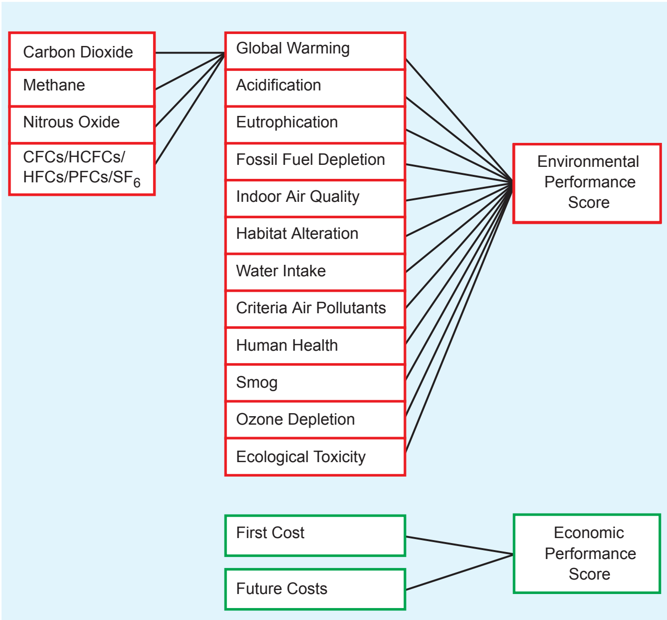

Figure 3.1. Example of impacts to be accounted when taking decisions about the introduction of new technologies or products (Lippiatt, 2002 adapted by authors).

3.2.1.1 Emissions by fluid life stage

Fluid manufacture [1]
The manufacture of fluids requires feedstock materials, which are sourced, produced and used worldwide. Emissions from these feedstock materials, their intermediates and the end substance can occur in chemical processing plants. For the production of many HFCs, these direct emissions can be significant in terms of CO_2 equivalent (on a GWP(100) basis – see Section 3.5.1). For example, the substances emitted during the production of HFC-227ea were estimated to amount to 120 kg CO_2-eq kg^{-1} of material manufactured (Banks *et al*., 1998), whereas for HFC-134a this figure was relatively low with estimates ranging from 2–40 kg CO_2-eq kg^{-1}. (McCulloch and Lindley, 2003 and Banks and Sharratt, 1996, respectively). These values are strongly dependent on the fluid manufacturing process and the integrity of the chemical plant. The good design and operation of the plant can lead to lower emissions. It should be noted that some of the intermediate substances might be ODSs (although these are converted into the end product without being emitted). For example CFC-114a, HCFC-133 and HFCF-124 are used in particular routes for the manufacture of HFC-134a (Frischknecht, 1999). The emissions of GHGs are significantly less for alternative fluids. HC-290, HC-600a and HC-1270 are generally extracted from natural gas mixtures and leakage from the process plant will generally comprise a variety of hydrocarbons. Gover *et al*. (1996) estimate 0.14 kg CO_2, 0.5 g HC and 0.7 g methane emissions per kg of propane/butane, which equates to 0.2 kg CO_2-eq kg^{-1}, and data from Frischknecht (1999) are lower than this. Ammonia is normally produced from natural gas and emissions of GHGs will only comprise methane and CO_2. Frischknecht (1999) estimates between 1.5 and 2.3 kg CO_2 kg^{-1} ammonia produced, consistent with the value in Campbell and McCulloch (1998). CO_2 is a slightly different case, as commodity CO_2 is generally a recovered byproduct from numerous other chemical manufacturing processes and it is therefore difficult to specifically attribute emissions to CO_2. Frischknecht (1999) reports emissions of CO_2 and methane, equivalent to 0.2 kg CO_2 kg^{-1} CO_2 produced.

Distribution of fluids
Once manufactured, fluids can be shipped nationally or internationally, often as bulk shipment or in individual cylinders. Typically, national or regionally organized distribution chains deliver bulk quantities to product manufacturers or transfer the substances into smaller containers for use by manufacturers and service companies, in the case of refrigerants and solvents. The distribution chain stops when the substance enters into the management or control of the 'user', such as a manufacturer or a service company. Losses normally occur during the transfer of fluids, connection and disconnection of hoses, and leakage from containers and pressure relief devices. These losses tend to be relatively small in relation to the large quantities of materials handled (Banks *et al*., 1998), as transfer operations take place under carefully-controlled conditions and are subject to international regulations for the prevention of releases (e.g. UN, 2002; IMO, 2000).

Manufacture and distribution of products
HFCs and alternative fluids are generally used in the manufacture of refrigeration systems, foams, aerosols and fire protection equipment, whereas solvent applications (e.g. cleaning) tend to apply fluids directly on-site during the in-use stage. The manufacture of refrigeration products requires transfer of the fluid. Losses normally occur due to the connection and disconnection of hoses and valves. Emissions also originate from storage vessels and the associated piping, but these are less frequent.

Some sources of emissions are specific to certain applications and products. For example, refrigerants are often used to rinse out air, moisture and other contaminants from refrigeration equipment to ensure internal cleanliness prior to charging. Moreover, the refrigerant may also be employed as a tracer for the detection of leaks. Equipment leaks may be found after charging of the refrigerant, in which case further emissions will occur during the recovery and evacuation process prior to repairing the leaks. During the manufacture of foams, fluids are used as blowing agents. The blowing-agent emissions during the preparation of foam formulations, when the blowing agent is mixed with other raw materials such as polyols, are low due to the use of closed systems. Depending on the type of foam

[1] Only direct emissions from the production process are considered here and not indirect emissions from electrical energy requirements.

Table 3.1. Percentage contribution of direct (HFC) emissions to total lifetime greenhouse-gas emissions in various applications (emissions associated to functional unit) – selected indicative examples.

Application	Method applied	HFC emissions as percentage of lifetime systemgreenhouse-gas emissions (using GWP-100)	Characterization of system and key assumptions	Publication
Mobile Air Conditioning	TEWI	**40–60%** – Current systems (gasoline engine) **50–70%** – Current systems (diesel engine)	Passenger vehicle; HFC-134a Sevilla (Spain)	Barrault *et al*. (2003)
Commercial Refrigeration	LCCP	**20–50%** – for a wide range of sensitivity tests on leakage rate, energy efficiency and energy supply	Direct Expansion Refrigeration Unit; Supermarket (1000m^2); HFC-404A; Germany	Harnisch *et al*. (2003)
Domestic Refrigeration	TEWI	**2–3%** – No recovery at end-of-life	European standard domestic refrigerator; HFC-134a; World average electricity mix	Chapter 4 of this report
Insulation Foam of Domestic Refrigerators	LCCP	**6%** – with 90% blowing agent recovered at disposal **17%** – with 50% blowing agent recovered at disposal	HFC-245 fa; Europe	Johnson (2004)
PU Insulation Foam in Refrigerated Truck	LCCP	**2%** – with full recovery of HFC at disposal **13%** – without recovery of HFC at disposal	Refrigerated Diesel truck; Germany	Harnisch *et al*. (2003)
PU Spray Foam Industrial Flat Warm Roof	LCA	**13%** – with full recovery of HFC at disposal **20%** – without recovery of HFC at disposal	4 cm thickness; HFC-365 mfc; Germany	Solvay (2000)
PU Boardstock in Private Building Cavity Wall	LCA	**4%** – with full recovery of HFC at disposal **17%** – without recovery of HFC at disposal	5 cm thickness; HFC-365 mfc; Germany	Solvay (2000)
PU Boardstock in Private Building Pitched Warm Roof	LCA	**10%** – with full recovery of HFC at disposal **33%** – without recovery of HFC at disposal	10 cm thickness; HFC-365 mfc; Germany	Solvay (2000)

and process, either a small fraction (rigid closed cell foam) or the entire blowing agent (flexible open cell foam) is emitted during the manufacturing process. The foaming usually takes place under ambient atmospheric conditions. The blowing agent emitted from the foaming process mixes with the air and is then vented or incinerated. Aerosols are generally charged in factory premises and, as for refrigerating systems, the disconnection of charging heads results in small releases. Cleaning machinery is occasionally filled with solvent, although emissions tend to be minimal at this stage because fluids with a low vapour pressure are generally used.

Use

The in-use stage of the product lifetime tends to result in the greatest emissions for most applications, particularly for refrigeration, aerosols, solvents and fire protection systems. For refrigeration and air-conditioning systems, for example, in-use emissions can vary widely depending on the service and disposal practices as well as other operational and environmental factors not intrinsic to the technology. Emissions from domestic, commercial and industrial refrigerating equipment generally originate from failures in system components or from the handling of refrigerant during servicing, with the size and frequency of leaks depending upon several factors. External factors include usage patterns, frequency of equipment relocation, weathering and aggressive environments, repair quality and frequency of preventative maintenance. Rapid fluctuations of temperature or pressure and excessive vibration of piping, joints and so forth, due to fan motors and compressors or other external sources are major causes of in-use leakage. Other integral aspects are associated with the design and construction of the equipment. The design quality of the equipment and the use of suitable components have a significant impact on leakage rates. Control systems are also responsible for emissions, such as pressure-relief devices. Most industry guidance on emissions focuses on leak prevention for the in-use stage (e.g., see Institute of Refrigeration, 1995; Butler, 1994; ETSU, 1997). The multiple factors contributing to emissions of refrigerant often lead to a fairly broad distribution of net leakage rates for individual pieces of equipment. Figure 3.2 shows an example

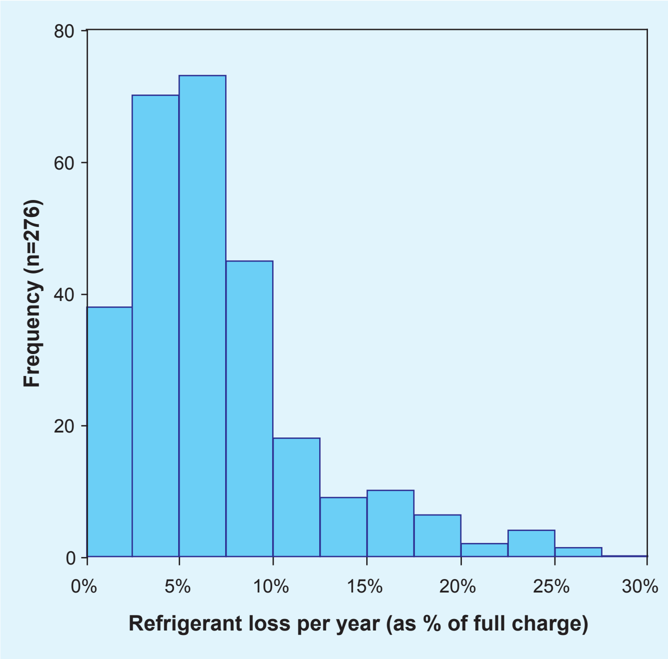

Figure 3.2. Distribution of annual leakage rates of mobile air conditioning systems in a fleet of 276 European passenger vehicles (after Schwarz & Harnisch, 2003.

from a survey carried out on mobile air-conditioning systems in Europe (Schwarz and Harnisch, 2003). A similar distribution is seen with supermarket systems (Radford, 1998). It is clear that the mean leakage rate for an equipment population can result from a broad distribution that includes many very tight, a large number of fairly tight and a small number of very leaky systems.

Decision-makers should realise that, in general, a leakage rate is not necessarily intrinsic to a certain technology but can also strongly depend on a number of environmental and operational factors. If properly understood, these factors can be systematically influenced to reduce emission levels. Whilst the quality of maintenance and repairs to equipment influence the leakage during operation, the actual handling of refrigerant may also lead to significant emissions, for example the removal of fluid from a system and the subsequent recharge. The degree of leakage is strongly dependent on the behaviour of the personnel and the tools they use, and will range from the minimum (that associated with residual gas within hoses and the system) up to quantities exceeding the system charge. Despite the legislation against venting in a number of countries, practices frequently prevail in which the whole system is vented, leak-tested with the fluid (possibly several times until all leaks are repaired) and flushed with the fluid before final recharging. Poorly connected hoses and fittings, and poor-quality recovery equipment can significantly contribute to high emissions.

The majority of emissions from aerosols, fire protection systems and solvents also occur during the in-use stage, although these are intentional since a release is part of the functionality of the equipment. Emissions from aerosols are simply a function of the amount of propellant used. Fire protection systems produce emissions upon demand, as is the intention, although undesired emissions occur from false alarms or faulty signals, or from mandatory system qualification tests that require full system discharge. Sometimes training also involves the operation of the fire protection system. Within the use phase of certain applications, such as fire protection systems, equipment servicing and maintenance may require the removal of fluid from a system and subsequent recharge, and emissions associated with this. Fire protection systems also exhibit slow passive emissions throughout the in-use stage, particularly in the case of high-pressure cylinder systems. Similarly systems that are being maintained can produce significant emissions if the system is accidentally initiated, or when servicing of the systems requires checking and confirmation of operation. Processes that use solvents generally lead to emissions as a result of residual fluid evaporation of treated items, and to a lesser extent whenever equipment is opened as part of its use.

Annual emissions from foams are generally minor during the in-use stage. The blowing agent in closed cell foams is released over time and typically only part of the blowing agent/insulant will be released during the useful life of the product. Caleb (2000) has calculated emission factors for different rigid foams based on a survey and the collection of data from emission factors reported in the literature. Lee and Mutton (2004) recently did the same for extruded polystyrene or XPS foam.

Decommissioning

Fluids may be vented or recovered during the decommissioning of refrigeration equipment, unexpelled fire protection systems and equipment using solvents. Over the past decade the price of recovery equipment has fallen significantly and the sales of such equipment have expanded, indicating that recovery has become much more widespread than was the case during the 1980s and first half of the 1990s. Blowing agents from foams and propellant from aerosols can also be recovered at end-of-life, but current methods have a low effectiveness. Emission levels of refrigeration and air-conditioning systems, and of foam applications are very sensitive to disposal practices.

For refrigerants, fluids from fire protection systems and solvents, the sources of emissions associated with removal at end-of-life are the same as those associated with normal handling, as discussed previously for the servicing aspect during the in-use stage. Fluids used to be vented when equipment was decommissioned but where legislation has been introduced, the expected practice is to recover the fluid. If the fluid is recovered, it may be re-used (in its recovered form), recycled (using on-site machinery) or taken back to the supplier or recycling centre for cleaning (and re-use) or disposal. Uncontaminated fluids can normally be reused and whether a fluid can be cleaned on-site or has to be returned to the supplier, depends on the type and degree of contamination and the process needed to return it to the purity of virgin fluid. However, in many situations, the resources required to clean up contaminated refrigerant rarely outweigh the risks and benefits to the service company. Therefore in most countries recovery rates have remained low if the chemical to be recovered is relatively inexpensive. Some suppliers or governments (e.g. Australia) have introduced cash incentives for the return of 'minimally-contaminated' refrigerant, but the success rate of such schemes is still unknown.

In the case of rigid insulating foams, the majority of blowing agents remain in the foam until end-of-life. Some rigid insulating foams such as 'board stock' and 'sandwich panels' can be recovered or re-used if they are not adhered to substrates or can be easily separated from these. A similar approach can be used with aerosol cans that contain residual propellant, although this procedure is not normally used.

Disposal

Following the recovery, and potentially recycling and reclamation, of refrigeration equipment, fluids meant for disposal are stored ready for destruction. The handling and storage of refrigerants and fire protection system fluids, solvents and recovered aerosol propellants prior to destruction can lead to emissions in the same way as in the distribution of fluids stage.

In the case of rigid insulating foams, the disposal is complicated because the foams are only a small part of overall systems such as a refrigerator or a building. Refrigerator foams can be shredded and incinerated to destroy all blowing agents. Alternatively they can be sent to landfills, where the blowing agents will slowly be emitted and/or decompose (Kjeldsen and Scheutz, 2003).

In general, destruction by incineration produces a small amount of emissions (of the original material). Destruction (or destruction and recovery) efficiencies are typically between 99% and 99.99%, resulting in 0.1−10 g released per kg of material (UNEP-TEAP, 2002). Gases such as CO_2, resulting from the combustion of fuel and fluid, are also emitted.

3.2.1.2 Types of emission

Table 3.2 identifies the types of emission common to the various applications in the subsequent technical chapters. These can be categorized into four general groups. Mitigation of emissions for each category requires attention for a particular process within the life of the equipment: Material selection (passive), mechanical design/construction (rupture), technician training (handling) and usage patterns (intentional/functional).

Passive

Passive emissions are generally small, 'seeping' leaks that occur constantly and are normally the result of permeation through construction materials and metal fatigue. This applies in particular to refrigerants, fire protection system fluids and aerosols when materials gasket, plastics and elastomers for seals and hosing are used. Emissions are minimized by selecting the correct materials for the fluids used. In making this choice, the influence of other fluids within the mixture such as refrigeration oils and aerosol fragrances, which can affect permeability, should also be considered. In rigid insulating foams, the passive emission of blowing agents occurs through diffusion. The diffusion coefficients of HFCs through the rigid insulating foams vary considerably, dependent on the type of blowing agent. The use of non-permeable facer materials such as aluminium foils and metal skins can significantly reduce the diffusion of blowing agents. Passive emissions typically occur throughout all stages of the fluid and foam life, but as they are relatively constant, they predominate during the in-use stage.

Table 3.2. Sources of emissions by type and application.

Application	Production				Use				Decommissioning				Disposal			
	Passive	Rupture	Handling	International	Passive	Rupture	Handling	International	Passive	Rupture	Handling	International	Passive	Rupture	Handling	International
Refrigeration		✓	✓	✓	✓	✓	✓	✓			✓	✓			✓	✓
Air conditioning		✓	✓	✓	✓	✓	✓	✓			✓	✓			✓	✓
Mobile air conditioning		✓	✓	✓	✓	✓	✓	✓			✓	✓			✓	✓
Foams			✓	✓	✓				✓		✓				✓	✓
Aerosols			✓	✓	✓	✓		✓			✓	✓		✓	✓	✓
Fire protection			✓	✓	✓	✓	✓	✓			✓	✓			✓	✓
Solvents			✓	✓	✓	✓		✓			✓	✓		✓	✓	✓

Note: Fluid manufacture and distribution are excluded from this table since they do not pertain to any one specific application.

Rupture

Ruptures are accidental breaks in pressure systems, such as fractures in pipework, vessels and components. These are normally associated with fluids under high pressure and therefore tend to occur throughout most stages of the fluid life. Ruptures can result from external forces applied to components, inherent material weaknesses, the influence of pressure and temperature changes, vibration, the ageing of materials and corrosion. Large ruptures are generally the most notable type of leaks and tend to cause rapid and often complete release of the fluid. Rupture leaks or emissions do not apply to foam because the pressure differential within and outside the foams is very small. Ruptures can be minimized by appropriately designing piping and components to account for anticipated stresses, protecting against external impact and avoiding a chemically aggressive environment.

Handling

Handling emissions are unintentional releases that occur with human intervention, for example, where a fluid is being transferred into or out of equipment and complete recovery is impractical. Residual amounts of fluid occur in transfer hoses, within components and systems following recovery, and absorbed in certain materials such as oil. The fluid will subsequently migrate to the atmosphere when hoses are disconnected or systems are opened following recovery. Such releases occur throughout the life of the fluid regardless of the application, but a lack of training and insufficient awareness of the environmental impact of fluids means that personnel are less likely to mitigate emissions when handling them.

Intentional/Functional

Intentional releases are determined by human activity and may be unnecessary or required because of the function of the application (e.g. aerosols, fire protection). Unnecessary intentional releases occur where the operator chooses to directly release the fluid to the atmosphere. Examples include venting where the fluid is not recovered following removal from an application, the fluid being released directly through opening valves or cutting into pipe work, or the operator employing the fluid for ulterior uses such as blowing dust from pipes, and so forth.

Functional emissions occur specifically with fire protection, aerosols and some solvent uses. In situations where the fluid is within storage facilities, or within pressure systems during the in-use stage, intentional releases can occur in response to uncontrolled circumstances, for example, when pressure relief devices vent in the event of fire. Similarly, fire protection systems may release fluid in response to false signals from heat, smoke or light detectors, thus discharging the whole system.

3.2.1.3 Measurement and estimation of emissions

Quantifying emissions from a specific application is useful for several purposes, including the retrospective environmental impact assessment or the evaluation of operating costs. Unfortunately for most applications it is difficult to measure the field leakage and even where this is possible, the measurement is imprecise. Laboratory studies are largely impractical for most applications, for example large supermarket refrigeration systems that are built and maintained by a number of different companies. However, emissions from foams are usually less sensitive to external conditions and so laboratory measurements are normally highly appropriate. Releases during fluid manufacture, fluid distribution and the manufacture/distribution of equipment would normally be measured by monitoring the mass flow of material into and out of facilities. The same applies at end-of-life, when recovered fluid is returned to suppliers and delivered to recycling or incineration facilities.

Since releases at the in-use stage tend to predominate, these are more frequently monitored. The problem with existing methods such as gas detection is that they do not measure the mass of fluid released; concentrations of leaked gas detected indicate the presence of a leak, but do not permit this to be quantified (Van Gerwen and Van der Wekken, 1995). Recent developments in leak detection for refrigerating systems include intrinsic detectors, where a reduction in refrigerant inventory is measured within the system (as opposed to measuring the presence of refrigerant outside it) (Peall, 2003, www.nesta.org.uk/ourawaardees/profiles/3763/index.html). Such an approach is particularly useful for accurately measuring the loss of charge but does not provide information on losses from handling activities. The most accurate method is to record the mass usage of the substance. For refrigerating equipment, fire protection systems and solvent use, this involves tracking the quantities of chemicals that are acquired, distributed and used to fill a net increase in the total mass (charge) of the equipment. Quantities not accounted for are assumed to have been emitted. Entities that contract equipment maintenance to service companies can estimate their emissions by requesting the service company to track the quantities of refrigerant recovered from and added to systems.

Different approaches can be used to prediction emissions associated with particular equipment or systems. The least accurate but most simplistic approach is to apply annual leak rates (% yr^{-1}) for the appropriate sector or equipment types to the mass of fluid used. However, these are generally approximated using bottom-up methods, combined with limited measured data and industry interviews (e.g. March, 1996). At best, leak rates may be found for equipment manufacture, aggregate in-use stage and end-of-life recovery. More detailed analyses may be conducted by calculating releases from each element throughout the equipment life. This also depends on good information about the flow of material throughout its life, data on component dimensions and knowledge about the behaviour of technician handling (US EPA, 1995). For example, Colbourne and Suen (1999) provide empirically-derived emission indexes for the leakage of different components and different servicing frequencies in order to estimate leakage for a whole system. With this more detailed approach, the actual design of systems and equipment can be more accurately assessed and 'emission optimization' can be applied to the design and operation.

Nevertheless, it is known that leakage rates are highly erratic and for two similar systems these may vary from 0% to over 100% yr^{-1}.

The emission of foam-blowing agents through diffusion can be derived from model calculations (Vo and Paquet, 2004; Albouy *et al*., 1998). Alternatively, the residual quantity of blowing agents can be determined analytically, although caution must be exercised when using these measurements to estimate in-use emissions. Although the emission of the blowing agent out of a well-defined foam system (e.g., a refrigerator or a piece of rigid foam) can be estimated, obtaining accurate emissions from the foam sector remains difficult due to the variety of foams, blowing-agent initial concentrations, diffusion rates of specific blowing agents, product thicknesses, densities, usage conditions and cell structures.

Direct measurement of greenhouse gas and other fluid emissions is only possible in a few cases and so the values described as 'real' data have to be calculated from secondary data. These calculations should conform to the standard methodologies already developed for emissions trading, which cover refrigeration and air-conditioning systems and chemical processes (DEFRA, 2003), and the standards and guidance for greenhouse-gas emissions inventories (IPCC, 1997; IPCC, 2000a).

The IPCC Good Practice Guidance on National Greenhouse Gas Inventories published in 2000 (IPCC, 2000a) includes three methods for estimating emissions of ODS substitutes. The tier 1 method that equates emissions to consumption (potential emissions), the tier 2a bottom-up method that applies country-specific emission factors to estimates of equipment stock at different life-cycle stages, and the tier 2b top-down method that uses a country-level, mass-balance approach. For sectors where the chemical is banked into equipment, the tier 1 method is significantly less accurate than the other two approaches. This is particularly the case where the equipment bank is being built up and this is precisely the current situation for air conditioning and refrigeration equipment during the transition from CFCs and HCFCs to HFCs. In this situation, most of the chemical consumed is used to fill new equipment volume (charge) rather than to replace emitted gas, and therefore the tier 1 method greatly overestimates emissions. To a lesser extent, the tier 2b country-level, mass-balance approach is also inaccurate during the period of bank building, but in this case, the error is an underestimate (see the discussion in Section 3.2.1.3 for an explanation of this underestimate). That is why the IPCC recommends supplementing the tier 2b approach with the tier 2a emission-factor based approach. The disadvantage of the tier 2a approach is that for the first few years of equipment life, the emission factors will necessarily be based on engineering estimates rather than empirical experience. However, when the first cohort of equipment is serviced, the emission factors can be corrected as necessary. Ultimately, when the HFC-using equipment starts to be retired, the tier 2b method can be used on its own with a high level of accuracy.

More detailed requirements for calculations are stated in IPCC (1997). IPCC (2000a) should be consulted for additional guidelines on emission estimation methods, particularly for the different sectors.

3.2.2 *Indirect emission*

This section examines aspects related to emissions arising from the energy consumption associated with the manufacturing of products and their components, the use of these products during their useful life and their disposal. The use phase is outlined for cooling applications, heat pumps and foams, as this phase usually dominates the energy consumption of these systems. More application-specific energy aspects are covered in the specific sections of Chapters 4 to 10 of this report.

3.2.2.1 Use phase

ODS substitutes are typically used in cooling applications and thermal insulation foams. For aerosols, solvents and fire protection, the energy consumption during the use phase is not relevant.

Cooling applications and heat pumps

The refrigeration, heat pump and air-conditioning sectors use different approaches to establish and compare energy efficiencies for various technologies:

- Modelled efficiencies based on modelled coefficients of performance (COP);
- Measured efficiencies of products in the research and development phase (established under standard test conditions)[2];
- Measured efficiencies of products in mass productions (established under standard test conditions);
- Measured consumption under representative real conditions.

The coefficient of performance (COP[3]) of a refrigerating plant, product or system is a key parameter for characterizing the energy efficiency of a process. It is the ratio of refrigerating capacity to the input power required to operate the compressor, pumps, fans and other ancillary components.

$$COP = Q_0 / P \qquad (3.1)$$

Where:

Q_0 is the refrigerating capacity (cooling mode) or heating capacity (heating mode) including an allowance for losses in any secondary circuit (kW), and

[2] It is important that the standard conditions represent the situation in which the equipment will be used; for example it would not be appropriate to use standard test results gained at an ambient temperature of 15°C when the real ambient temperature of operation of the equipment is 35°C.

[3] In European standards and some ISO standards the term EER (Energy Efficiency Ratio) is used for the cooling mode of the cycle and COP (Coefficient Of Performance) is used for the heating mode. For the purpose of this report only one term is used, COP. Where this term is used, it should be specified whether it relates to cooling or heating.

P is the total power consumption (kW) of the compressors, controls, fans and pumps required to deliver that capacity to the place where it is used.

The COP primarily depends on the working cycle and the temperature levels (evaporating/condensing temperature) but is also affected by the properties of the refrigerant and the design of the system. Energy consumption estimated from known models does not usually take into account the effects due to different ‘real-world’ handling practices, imperfect design, assembly, capacity control and maintenance. Small fluid leakage, for example, not only impacts direct emission but also indirect emission due to a decrease in the COP of equipment. Figure 3.3 gives an example of the real world spread of measured energy consumptions for a large group of homogenous refrigeration systems. Another typical example is the use of capacity control technologies to optimize the energy consumption. Good capacity control results in smaller pressure differences (evaporating/condensing temperature) leading to improvements of the overall energy efficiency of the system.

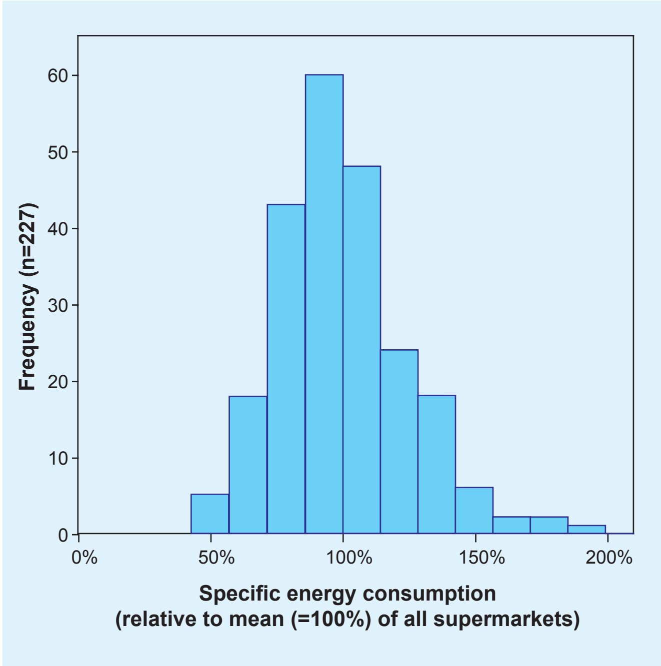

Figure 3.3. Distribution of measured specific energy consumptions (originally expressed as kWh d^{-1} m^{-1} of cooled display cases) expressed as percentage of the mean for 227 standard stores using standard HFC technology of a German supermarket chain – after Harnisch *et al.* (2003).

Insulation foams

There are two fundamental approaches to assess the effects on energy consumption of using insulation materials with differing insulation properties as a result of a changed blowing agent (Table 3.3).

Further the specific usage pattern of the system should be noted and addressed if it is material to the calculation. One example might be the effect of day to night temperature changes on a cold store that has traffic through it 24 hours per day as opposed to one that is shut up all night. Both approaches need to be documented with references to standard calculation methods and sources of information.

Approach B in Table 3.3 depends on more assumptions than approach A and is conceptually more challenging. However circumstances can arise in which thickness compensation is technically not possible due to space constraints and then approach B is the only feasible method. Even if partial thickness compensation is possible, the calculation of energy impacts will still require approach B.

In general these comparisons are limited to identical systems where only one element has been changed. Comparisons between completely different systems are much more difficult

Table 3.3. Comparison of two approaches for comparing the impact of blowing agent choice on energy consumption.

Approach A) Thickness compensation: The thickness is increased for any loss of insulation value so that unchanged energy consumption is assumed to be achieved by a material penalty. This may have an environmental impact due to increased direct emissions and the energy used for production. However, for the energy consumption during the usage phase, the key requirements are relatively simple and involve characterization of: • The functional unit and its desired service (e.g. required common additional heat resistance R value m^{-2} of application and time); • The insul respective thickness and density or mass); • The insulation properties of the foam(s) using a test appropriate to the duty (e.g. respective thermal conductivity values).
Approach B) Comparative energy modelling: Where it is not possible to com pensate for a change in insulation value, the energy consumption of the system in which the foam is used is calculated for both the reference case and alternative case. This is a more complex process and, in addition to the parameters outlined above, it will require definition of: • The type and efficiency of the process supplying heat or cold (to accommodate change in efficiency with temperature); • The appropriate ambient conditions and the internal temperature profile require or alternatively a description of an appropriate proxy (for example heating or cooling degree days); • Internal sources of heat or cold and how the demand will change with temperature.

to interpret. Examples of comparisons of different foam types, where the model assumptions are clear and do not compromise the results, are given in Caleb (1998, 1999), Enviros March (1999), ADL (1999), Krähling and Krömer (2000), Harnisch and Hendriks (2000) and Harnisch *et al*. (2003).

3.2.2.2 Production energy of fluids and fugitive emissions

Table 3.4 details the small number of estimates of production energy (also known as embodied energy) and fugitive emissions associated with the production of the materials used in systems covered by this report. These estimates are also summarized and applied in Frischknecht (1999a and 1999b) and Harnisch *et al*. (2003). It is worth noting that the newer study shows lower values for HFC-134a due to more widespread application of vent gas treatment to destroy 'fugitive' HFC streams (in previous studies these were emitted into the atmosphere). In-use emissions usually dominate environmental impact and production energy, whereas fugitive emissions only make small contributions.

3.2.2.3 Indirect emissions from energy use

Indirect emissions (of carbon dioxide) from the energy used to operate a system comprise those arising from the generation of the electricity consumed (for example by the compressor, controls, pumps and fans of a building air-conditioning system) and any fuel used directly by the system (e.g. gas used for gas-driven compressors, fuel used by absorption systems or the additional gasoline usage associated with automobile air conditioning). The total lifetime emission of carbon dioxide from the energy used to operate the system (E_I) is:

$$E_I = Q_E \text{ x } I_E + \sum(Q_{Fi} \text{ x } I_{Fi}) \qquad (3.2)$$

Where:
Q_E is the total lifetime use of electricity;
I_E is the carbon dioxide intensity of electricity production (from Table 3.5);
Q_{Fi} is the total lifetime use of fuel *i*, and
I_{Fi} is the carbon dioxide intensity of that fuel (from Table 3.5)

Carbon dioxide emissions associated with the generation of electricity vary greatly between countries depending on the specific mix of generation technologies and fuels (e.g. coal, natural gas, combined cycle systems, hydroelectricity, etc.) used. Increasingly complex calculations could be performed to define the minute details of energy-related emissions of carbon dioxide and other greenhouse gases. However for the generic approach described here, it is assumed that the most important emission is carbon dioxide and that the methods employed by the International Energy Agency (IEA) will give internationally consistent estimates. Accordingly, national and regional carbon dioxide intensities of electricity are shown in Table 3.5. These intensities are calculated as the ratio of national carbon dioxide emission from electricity generation, taken from IEA (2002b), to the quantity of electricity used nationally, obtained from IEA (2002a) or IEA (2003). The IEA statistics take into account electricity trading between countries, in the form of an annual average.

For those countries or regions not shown in Table 3.5, the national carbon dioxide intensity of their electrical power (I_E) may be calculated as the sum of the total of each fuel used in electricity generation, multiplied by its carbon dioxide intensity (also quoted in Table 3.5), divided by the total national quantity of electricity *delivered* to customers.

$$I_E = \sum (Q_{Fi} \text{ x } I_{Fi}) / D_E \qquad (3.3)$$

Where:
Q_{Fi} is the total annual quantity of fuel *i* used in electricity generation and I_{Fi} is the carbon dioxide intensity of that fuel (from Table 3.5), and

Notes:
a. Regions as defined in IEA (2002a) and IEA (2003).
b. Carbon dioxide from "Public Electricity and Heat Production"5 (units Mtonnes CO_2) in summary tables of IEA (2002b), divided by Total Final Consumption electricity and heat6 given as ktonne Oil Equivalent in IEA (2002a), further divided by 11.63 to convert to kg CO_2 kWh^{-1}.
c. Carbon dioxide as in 2 above, divided by Total Final Consumption[4] given as GWh in IEA (2003), multiplied by 1000 to convert to kg CO2 kWh^{-1}.
d. Values from Table 3 of IEA (2002b) multiplied by 44/12 to convert to mass of CO_2.
e. Using this category has the effect that all energy inputs to systems that generate electricity and heat are counted against both the electricity and heat generated.
f. Total Final Consumption is electricity or heat available at the consumer net of transmission and distribution losses.

D_E is the total annual national delivery of electricity. Table 3.6 shows examples of the application of this method.

Where there is a nationally agreed energy plan for the future, figures from this may be used for assumptions about future indirect emissions from energy use.

3.3 Categories of costs

The cost of climate change mitigation is an important input to decision-making about climate policy goals and measures. This section provides an oerview of key concepts and assumptions that can be applied to the assessment of policy options related

Notes:

Values in italics are constants available from standard tables (see Table 3.5 here)

A. Both the calorific value and the carbon content (and thus emission factor) vary with the quality of coal.

B. More than one quality of coal may be used (and separate rows should be used, then added together).

C. Calorific value varies between sources and should be determined by testing.

D, F, H, J. CO_2 emission factors are shown in Table 3.5

K. The value in K is equal to (B x C x D + E x F + G x H + I x J) divided by 1000.

L. This is the total electrical production minus only the amount lost in distribution.

M. The carbon intensity is equal to K divided by L.

to technologies and production processes using fluorinated gases. The use of consistent and well-defined cost concepts is recommended for the assessment of the various technologies and options described in detail in various parts of this Special Report, and for reporting the assumptions and concepts applied in mitigation studies in a thorough and transparent manner.

3.3.1 Introduction

Actions to abate emissions of fluorinated gases generally divert resources from other alternative uses, and the aim of a cost assessment is to measure the total value that society places on the goods and services foregone due to resources being diverted to climate protection. Where possible the assessment should include all resource components and implementation costs and should therefore take into account both the costs and benefits of mitigation measures.

A key question in cost analysis is whether all relevant dimensions (e.g. technical, environmental, social) can be measured in the same units as the costs (i.e. monetary). It is generally accepted that some impacts, such as avoided climate change, cannot be fully represented by monetary estimates and it is imperative that the cost methodology is supplemented by a broader assessment of impacts measured in quantitative and if needs be qualitative terms.

In any economic analysis of climate change mitigation, the cost of mitigation is calculated as a difference in costs and benefits between a baseline case and a policy case that implies lower emissions. Where possible, the definitions of the baseline and policy cases should include all major social, economic and environmental impacts (at minimum from GHG emissions and ODP emissions). In other words, the system boundary of the cost analysis should facilitate the inclusion of all major impacts. The system boundary can be a specific project, one or more sectors, or the entire economy.

The project, sector and macroeconomic levels can be defined as follows:

1. *Project*. A project level analysis considers a 'stand-alone' investment that is assumed not to have significant impacts on markets beyond the activity itself. The activity can be the implementation of specific technical facilities, demand-side regulations, technical standards, information efforts, and so forth. Methodological frameworks to assess the project level impacts include cost-benefit analysis, cost-effectiveness analysis and Life Cycle Assessment.

2. *Sector.* Sector level analysis considers sectoral policies in a 'partial equilibrium' context, for which all other sectors and the macroeconomic variables are assumed to be as given.

3. *Macroeconomic.* A macroeconomic analysis considers the impacts of policies across all sectors and markets.

Costs and benefits can be reported in present values or as levelized values (alternative ways to generate time-consistent values for flows of costs and benefits that occur at different points in time). Further details about these approaches can be found in Box 3.1.

This report focuses on project level cost analysis in particular because a); the scale of the mitigation policies analyzed can be considered small enough to exclude significant sectoral and economy-wide impacts; b) the basis for conducting a sectoral level cost analysis is weak since the literature does not include sectoral modelling studies for activities which involve the production and use of ODSs and their substitutes; c) and finally the current section is a first attempt to define consistent cost concepts applied to the assessment of climate change and ODS mitigation policies.

3.3.2 Direct engineering and financial cost approach

At the project level, the simplest cost assessment considers the financial costs of introducing a new technology or a production process that has lower emissions than the baseline case. Such practices can imply capital costs of new investments and changed operation and maintenance costs. When the system boundary is defined to include only the financial costs associated with the project implementation, some studies been termed this the direct engineering or financial cost approach.

Policy implementation can require upfront capital costs and changes (decreases or increases) in operation and maintenance costs compared with the baseline case over the lifetime of the project. Major categories of costs accounted in a financial cost assessment are capital, labour, land, materials, maintenance and administrative costs. The various costing elements need to be transformed into values that are comparable over the time frame and as such the cost assessment depends on assumptions about discount rates. The time dimension of costs can be dealt with using various policy evaluation approaches and an overview of some of those applied to the cost-effectiveness analysis of projects is given in Box 3.1.

3.3.2.1 Discounting

There are two approaches to discounting (IPCC, 1996b). One approach (known as ethical) gives special attention to the wealth of future generations and uses a social discounting rate. Another approach (known as descriptive) is based on the discount rates savers and investors actually apply on their day-to-day decisions and uses a higher, private cost discount rate. The former leads to relatively low rates of discount (around 2–3% in real terms) and the latter to relatively higher rates (at least 6% and in some case very much higher rates) (IPCC, 2001b, pp. 466).

For climate change, a distinction needs to be drawn between the assessment of mitigation programmes and the analysis of impacts caused by climate change. The discount rate applied in cost assessment depends on whether the social or private perspective is taken. The issues involved in applying discount rates in this context are addressed below. For mitigation effects, the

BOX 3.1 – The NPV and Levelized Cost Concepts

Guidelines for project assessment use a number of different concepts to compare the cost-effectiveness of projects. The most frequently used concepts are net present value (NPV) and levelized cost. These concepts basically provide similar project ranking.

The NPV concept
The NPV concept can be used to determine the present value of net costs, *NPVC*, incurred in a time period T, by discounting the stream of costs (C_t) back to the beginning of the base year (t = 0) at a discount rate I:

$$NPVC = \sum_{t=0}^{T} C_t / (1+i)^t$$

The levelized cost concept
The levelized cost represent a transformation of the *NPCV* into constant annual cost values, C_0, over the lifetime of the project. The levelized costs are calculated as a transformation of the *NPVC* using the formula:

$$C_0 = NPVC\left(i / \left(1-(1+i)^{-n}\right)\right)$$

where n is the time horizon over which the investment is evaluated.

The levelized costs can directly be compared with annual emission reductions if these are constant over the project lifetime.

The use of NPV and levelized costs as project ranking criteria is valid, given a number of assumptions:

NPV
An investment I_1 is more favourable than another investment I_2 if $NPVC_1$/*GHG reduction* < $NPVC_2$/*GHG reduction*. It should here be noticed that the use of NPVCs to compare the cost-efficiency of projects requires that some discounting criteria be applied to the annual greenhouse-gas emission reductions. The NPVC/GHG ratio can be used to rank investments with different time horizons.

Levelized cost
An investment I_1 is more favourable than another investment I_2 if the levelized cost of I_1 per unit of annual emission reduction is less than the levelized cost of I_2 per unit of annual emission reduction. The levelized costs should be calculated for similar investment lifetimes. The lifetimes of the investments if necessary can be made uniform by adding terminal values to investments with relatively long life time, or by replicating investments that have a relatively short lifetime.

country must base its decisions, at least in part, on discount rates that reflect the opportunity cost of capital. In developed countries, rates of around 4%–6% are probably justified (Watts, 1999). In developing countries the rate could be as high as 10–12%. These rates do not reflect private rates of return, which typically need to be considerably higher to justify the project, potentially between 10% and 25%.
For climate change impacts, the long-term nature of the problem is the key issue. The specific benefits of a GHG emission reduction depend on several factors such as the timing of the reduction, the atmospheric GHG concentration at the time of reduction and afterwards.. These are difficult to estimate. Any ‘realistic’ discount rate used to discount the impacts of increased climate change impacts would render the damages, which occur over long periods of time, very small.

3.3.3 Investment cycle and sector inertia

In the area of technologies associated with the manufacture and use of fluorinated gases, observations about replacement rates of old products have shown that it has been possible to undertake investments with a payback period as low as 1 to 5 years. This evidence suggests that from an economic and technical point of view[4], it is possible to rely on mitigation policies that are fully implemented over less than a decade. However, social structures and personal values also interact with society’s phys-

[4] There are some concerns about the capacity to maintain such fast technical transitions for future technical evolution in these sectors. Transition from CFCs to HCFCs was relatively easy because the chemistry was already known.

ical infrastructure, technology applications and institutions, and these combined systems have in many cases evolved relatively slowly. An example of such system inertia is seen in relation to the energy consumption for heating, cooling and transport, and the impacts of urban design and infrastructure. Markets sometimes tend to 'lock in' to specific technologies and practices that are economically and environmentally suboptimal, because the existing infrastructure makes it difficult to introduce alternatives. Similarly the diffusion of many innovations can be in conflict with people's traditional preferences and other social and cultural values (IPCC, 2001a, pp. 92-93).

At the same time, it should also be recognized that social and economic time scales are not fixed. They are sensitive to social and economic forces, and are influenced by policies as well as the choices made by individuals and institutions. In some cases behavioural and technological changes have occurred rapidly under severe economic conditions, for example during the oil crises of the 1970s (IPCC, 2001a, pp. 93). Apparently, the converse can also be true: In situations where the pressure to change is small, inertia is large.

Both of these issues should be considered when building scenarios about future GHG emissions from a sector. These lessons suggest that new policy approaches are needed. Instead of looking solely for least-cost policies given current preferences and social norms, policies could also aim at reshaping human behaviour and norms. This could support fast technology penetration and from a longer time perspective in particular, could imply cost reductions through learning and market development.

3.3.4 Wider costing methodologies – concepts

Up until now we have only considered the direct engineering and financial costs of specific technical measures. However, the implementation of policy options that mitigate climate change and ODSs will often imply a wider range of social and environmental impacts that need to be considered in a cost analysis.

3.3.4.1 Social and financial costs

In all work on costs, a basic distinction can be drawn between the social cost of any activity and the financial cost. Social cost is the full value of the scarce resources used in the activity measured from the point of view of society. Financial cost measures the costs from the perspective of a private company or an individual and bases its values on the costs that actually face these agents. A difference between social and financial costs arises when private agents do not take full account of the costs that they impose on other agents through their activities – such a cost is termed an external cost. Positive impacts which are not accounted for in the actions of the agent responsible, are referred to as external benefits.

External costs and benefits are distinct from the costs and benefits that companies or other private agents take into account when determining their outputs such as the prices of fuel, labour, transportation and energy, known as conventional company costs, and also from environmental costs usually accounted in more complete evaluations of company costs (see Table 3.7). Categories of costs that influence an individual's decision-making are referred to as private costs. The total cost to society is the sum of the external and private costs, which together are defined as social cost:

$$\text{Social Cost} = \text{External Cost} + \text{Private Cost} \qquad (3.4)$$

The scope of the social and private costs is illustrated in Figure 3.4.

External costs typically arise when markets fail to provide a link between the person who creates the 'externality' and the person who is affected by it, or more generally when property rights for the relevant resources are not well defined. Externalities do not necessarily arise when there are effects on third parties. In some cases, these effects may already be recognized, or 'internalized' and included in the price of goods and services. Figure 3.4 illustrates different subcategories of environmental costs, including external costs and private costs as faced by a private company. The centre box represents company costs that are typically considered in conventional decision-making. The next box (private costs) includes the typical costs plus other internal environmental costs that are potentially overlooked in decision-making, including regulatory, voluntary, up-front, operational, back-end, overhead, future, contingent and image/relationship costs. These 'private costs' include internal intangible costs (e.g., costs that could be experienced by a company related to delays in permitting, and so forth, and due to disputation with regulators and others). The box labelled societal includes environmental costs that are external to a company. These are costs incurred as a result of a company affecting the environment or human health, but for which the company is not currently held legally or fiscally responsible. These 'externalities' include environmental degradation and adverse effects on humans,

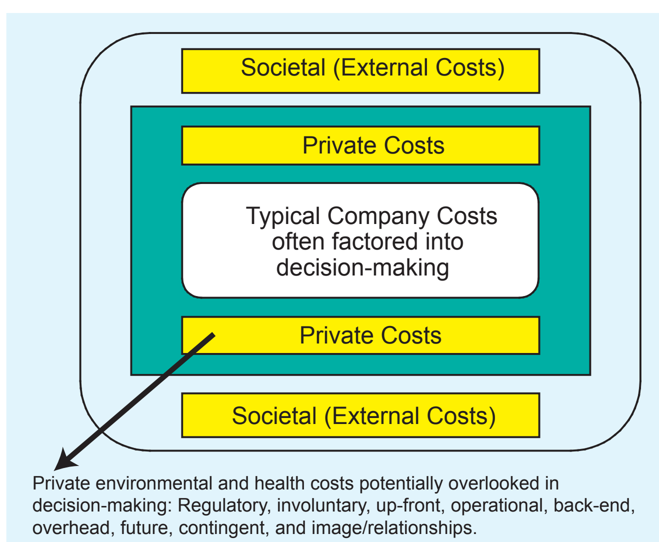

Figure 3.4. Scope of full costs (Adapted from US EPA, 1995).

Table 3.7. Examples of environmental costs incurred by firms.

Potential Hidden Costs		
Regulatory	**Upfront**	**Voluntary (Beyond Compliance)**
Notification	Site studies	Community relations/outreach
Reporting	Site preparation	Monitoring/testing
Monitoring/testing	Permitting	Training
Studies/Modelling	R&D	Audits
Remediation	Engineering at procurement	Qualifying suppliers
Record keeping	Installation	Reports (e.g., annual environmental reports)
Plans		Insurance
Training		Planning
Inspections	Conventional Costs	Feasibility Studies
Manifesting	Capital equipment	Remediation
Labelling	Materials	Recycling
Preparedness	Labour	Environmental studies
Protective equipment	Supplies	R&D
Medical surveillance	Utilities	Habitat and wetland protection
Environmental insurance	Structures	Landscaping
Financial assurance	Salvage Value	Other environmental projects
Pollution control		Financial support to environmental groups and/or
researchers		
Spill response	Back-End Costs	
Storm water management	Closure/decommissioning	
Waste management	Disposal of inventory	
Taxes/fees	Post-closure care	
	Site survey	
Contingent Costs		
Future compliance costs	Remediation	Legal expenses
Penalties/fines	Property damage	Natural resource damage
Response to future releases	Personal injury damage	Economic loss damages
Image and Relationship Costs		
Corporate image	Relationship with professional staff and workers	Relationship with lenders
Relationship with customers	Relationship with insurers	Relationship with communities
Relationship with investors	Relationship with suppliers	Relationship with regulators

Note. In upfront cost category, the centred box surrounded by dashed lines represents conventional costs, which are usually accounted.
Source: US EPA (1995).

property and welfare associated with emissions/activities that are performed in compliance with regulatory requirements. The figure does not directly portray the benefits that may be associated with alternative decisions.

3.3.4.2 Welfare basis of costs

The external effects described above cannot be valued directly from market data, because there are no 'prices' for the resources associated with the external effects (such as clean air or clean water). Indirect methods must therefore be used. Values have to be inferred from decisions of individuals in related markets, or by using questionnaires to directly determine the individuals' willingness to pay (WTP) to receive the resource or their willingness to accept payment (WTA) for the environmental good.

3.3.4.3 Ancillary costs and benefits

Projects or policies designed for GHG and ODS mitigation frequently have significant impacts on resource use efficiency, reductions in local and regional air pollution, and on other issues such as employment (IPCC, 2001b, pp. 462). When estimating the social costs of using technologies that impact climate change and/or ODS, all changes in cost arising from this activity have to be taken into account. If some of them imply a reduction (increase) in external costs, they are sometimes referred to as secondary, indirect benefits (costs) or ancillary benefits (costs).

3.3.5 Wider costing methodologies – cost categories

3.3.5.1 Project Costs

This item has already been discussed in the introduction of Section 3.3.2. However, the cost categories listed there may need to be adjusted when carrying out the wider cost methodology. Adjustments in land costs, labour, investments, materials, energy costs, environmental services and foreign exchange may be needed for private costs and external costs, and a detailed list is provided by Markandya and K. Halsnæs (2000).

3.3.5.2 Implementation cost

In addition to the above, the costs of implementation deserve special attention. Many aspects of implementation are not fully covered in conventional cost analyses (see Table 3.7). A lot of work needs to be done to quantify the institutional and other costs of programmes, so that the reported cost figures represent the full costs of policy implementation. As shown in Table 3.7, implementation costs depend on institutional and human capacities, information requirements, market size and the learning potential, as well as on market prices and regulations in the form of taxes and subsidies.

3.3.6 Key economic drivers and uncertainty

For various reasons cost estimates are shrouded by uncertainty and therefore any presentation of cost estimates should include transparent information about various keys to uncertainty that relate to both the baseline case and the new project case. Uncertainty in baseline cases is best dealt with by reporting cost estimates for multiple as opposed to single baselines. With this costs will not be given as single values, but as ranges based on the full set of plausible baselines (see for example IPCC, 2001b, pp. 30-37).

Uncertainties in cost estimates are related to both private and external cost components. Private cost figures tend to be less uncertain than external cost components, since the private costs primarily relate to market-based economic transactions. However, there is a particular uncertainty related to projections of future efficiency, and the costs and penetration rates of new technologies. One way to handle this uncertainty is to undertake a sensitivity analysis based on scenarios for high, low and medium case values (Markandya and Halsnæs, 2000). Another way of accounting is to consider some kind of 'learning curve', that is an expected cost reduction as a function of the increasing amount of products using the technology.

3.3.7 Other issues

3.3.7.1 Baseline Scenarios

Quite often the costs of a programme are evaluated against a situation where the programme is not implemented. This situation is defined by a baseline scenario, which tries to infer future conditions without the implementation of the programme. There are assumptions embedded in the baseline to forecast the future, for example, inefficient baseline, or 'business-as-usual' baseline. It is important to note that a programme's cost and benefit will vary according to this baseline scenario definition. For a mitigation programme, the cost will be larger if an economically efficient baseline is set rather than an inefficient one.

3.3.7.2 Macroeconomic costs

The cost of a programme can be measured using a macroeconomic analysis based on dynamic models of the economy. These models examine the impacts of a programme at an integrated level and allow for intersectoral effects. This means that they are more suitable for programmes large enough to produce impacts on other sectors of the economy.

On the other hand macroeconomic cost estimates generally provide less detail about technological options and externalities than project or sectoral cost estimates.

3.3.7.3 The equity issue

Equity considerations are concerned with the issues of how the costs and benefits of a programme are distributed and the climate change impacts avoided, as input to a more general discussion about the fairness of climate change policies. Equity concerns can be integrated in cost analysis by reporting the distribution of costs and benefits to individuals and society as a supplement to total cost estimates. Some authors also suggest applying income distribution weightings to the costs and benefits to reflect the prosperity of beneficiaries and losers (Ray, 1984; Banuri *et al*., 1996).

3.3.8 Conclusions

For most of the mitigation measures discussed in this Special Report, the specific measures (e.g. technical facilities, infrastructure, demand-side regulation, supply-side regulation, information efforts, technical standards) can be considered to have relatively small economic impacts outside of a narrow project border and can therefore be regarded as 'stand-alone' investments that are assessed using a project assessment approach. However, this does not imply that the cost assessment should solely limit itself to a consideration of the financial cost elements. A project system boundary allows a fairly detailed assessment of GHG emissions and the economic and social impacts generated by a specific project or policy. Accordingly various direct and indirect social costs and benefits of the GHG reduction policies under consideration should be included in the analysis.

Furthermore, it should be realized that as industrial competition increases, an increasing number of companies might become interested in using the most advanced production paradigms. For example, this was the case for lean production, an approach which evolved in Japan during the post-war period and implied greater flexibility in production and working partners. Many typical company features have included environmental concerns as well as broader issues of sustainable development as an evolving feature of the lean production paradigm.

In other words the companies have expanded the view about the boundaries of their own production.

Companies set boundaries around the activities they manage directly as well as those they do not control or manage. A distinctive feature of the lean production system has been an increasing transparency across firms that are dealing with different elements of the production chain. There has also been a tendency towards integrating management functions along the supply chain in order to examine the entire production chain for added value sources, irrespective of the current legal company boundaries along the chain. The application of information technology to business processes has facilitated the introduction of these new management systems. Without this the application of quantitative methods would have proved too complex (Wallace, 1996).

This new integrated management approach is illustrated in Figure 3.5. The figure shows a typical production chain, where the dotted line represents the boundary within the production process. Within that boundary, the management of the process may be integrated, irrespective of the number of companies involved or their exact legal relationship. This boundary might also include the extraction of raw materials, various product end-uses and even the disposal of the materials after use.

Every stage of production and consumption implies important environmental impacts. Companies are increasingly being required to explicitly manage these environmental impacts in response to formal regulations and pollution charges. Alternatively they might voluntarily adopt cleaner production technologies and tools, such as eco-auditing, in response to increasing expectations from society. Another driving force can be the increasing legislative liabilities of companies with respect to pollution. It is therefore useful for analysts to consider a system-wide company boundary that includes all stages of production in life cycle assessment, as shown in Figure 3.5.

3.4 Consideration of health and safety issues

Health and safety issues are an integral aspect of deciding the choice of fluids when alternatives are available, and the decisions can have far-reaching consequences for the workforce, domestic consumers, industry, the environment and the economy. Assessment methods for health and safety should first of all focus on minimizing negative health and safety impacts, and then consider risk management, policy and regulatory controls. This approach should be used for each step of the life cycle of the product including production, distribution, use, maintenance, repair and the end-of-life treatment such as destruction, re-use or recycling. Sometimes it can be wise to accept an increase in one life-cycle stage so as to arrive at an overall improvement in the impact accumulated over the life cycle. During the switch from ozone-depleting substances (CFCs and HCFCs) to HFCs, the health and safety risks of both groups of chemicals were similar. Here the main concern was energy efficiency and reliability. During the switch from higher GWP fluids to lower GWP fluids, health and safety often become a key issue. Some of the key considerations are examined in the following sections.

3.4.1 *Prevention of negative health and safety impacts*

Chemical exposure can cause or contribute to many serious health effects such as heart ailments, damage to the central nervous system, kidney and lungs, sterility, cancer, burns and rashes (US DoL, 1998). The impact of these effects includes lower productivity, absenteeism, increased health-care costs, litigation, and economic downturn at both the enterprise and national levels. Most countries have passed occupational health and safety laws in response to this, but the enforcement of such legislation is difficult, particularly in developing countries. This is borne out by the fact that only 5−10 % of workers in developing countries and 20–50 % of workers in industrialized countries (with a few exceptions) are estimated to have access to adequate occupational health services (Chemical Hazard communication: US Department of Labour (1998 revised). However, given the potential negative impacts in the absence

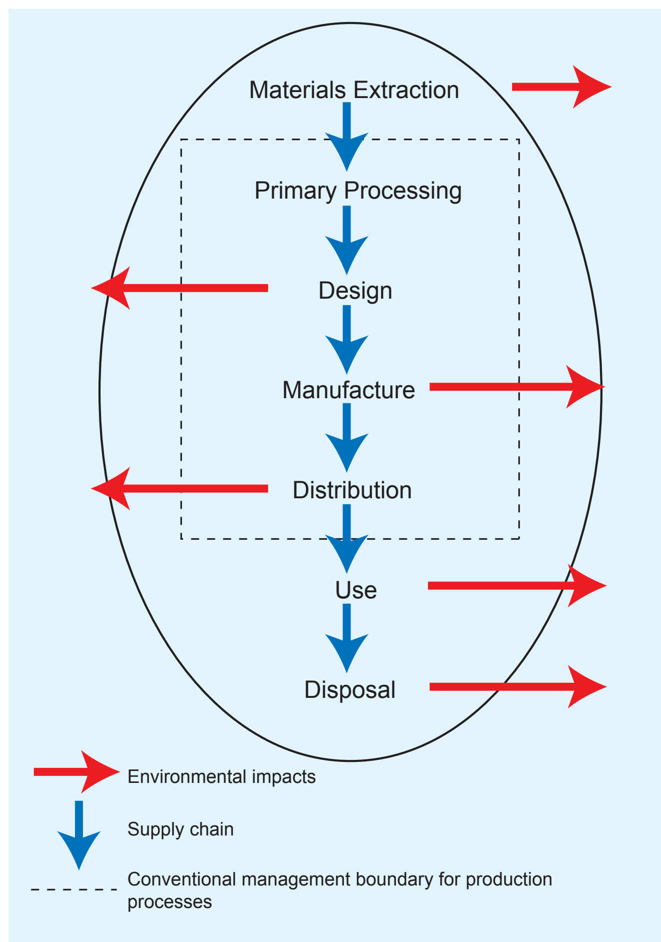

Figure 3.5. Environmental impacts along the supply chain (Wallace, 1996)

of adequate health and safety precautions, it is in the interest of both businesses and government to minimize these. Periods in which businesses are undergoing technological changes provide good opportunities to institute measures for preventing negative health and safety impacts on their workers and operations. They also provide governments with opportunities to implement measures to ensure that these matters are considered during the period of change.

3.4.2 Risk assessment of chemicals

Risk assessment is central to safety. It provides the scientifically sound basis for actions, including policy and regulatory actions to manage potential risks from the production, storage, transportation, use and disposal of chemicals. A number of parameters must be considered when undertaking risk assessments, such as chemical composition, stability and reactivity, hazards identification and classification, transportation, storage and handling, ecological impacts, physical and chemical properties, routes of exposure, effects of exposure, exposure limits, and toxicological information. As well as guiding the decision on the choice of a chemical to be used for a particular application, the assessment will also inform decisions on risk management as well as policy and regulatory controls.

3.4.3 Risk management of systems

Risk management is a broad term for the process that uses the outcomes of a scientific risk assessment to implement best practices, which are usually supported by appropriate policy and regulatory frameworks. A number of options are usually available for managing risk. These depend on the nature of the risk and the technological, economic and policy options available to address this. Effective risk management includes a wide range of measures such as information provision, training and/or retraining, risk assessment training, redesignated work practices, use of personal protective equipment, evaluation and monitoring of both the immediate and wider environments, redefinition of exposure limits and standards, and medical examinations.

3.4.4 Policy and regulatory controls

Most countries have occupational health and safety laws that require employers (as far as it is reasonable and practicable) to provide safe working environments and to develop and implement policies and measures to educate and protect their employees. In general, laws are developed on the principles of precaution and reasonableness, and these need to be adjusted when new processes, technologies or inputs are introduced into the economy that have health and safety implications not covered under the existing framework. Governments are responsible for ensuring that an appropriate regulatory and policy framework exists to protect human and ecological health and safety as well as property, and to ensure compliance. When such a framework and the associated legal requirements are compiled, the health and safety of the user, worker and those in the locality must be the main priorities. Product liability laws have been established in several areas of the world to protect users, workers and members of the public with respect to health and safety or any other damage. The liability legislation in a country is an important factor in the choice of the system and fluid chosen for the application, irrespective of what the safety standard specifies. When drawing up regulations, the combination of several regulatory requirements, including product liability, needs to be taken into account.

3.4.5 Health and safety criteria

For the purposes of this report, health and safety issues are considered under the following criteria:

Flammability: Ability to support combustion; a high capacity for combustion; burning velocity and expansion ratio.

Acute toxicity: Adverse effects are observed within a short time after exposure to a chemical. This exposure may be a single dose, a short period of continuous exposure, or multiple doses over a period of 24 hours or less.

Chronic toxicity: Adverse effects observed following repeated exposure to a chemical during a substantial fraction of an organism's lifespan. For human chronic toxicity typically means exposure over several decades; for experimental animals it is typically more than 3 months.

Carcinogenicity: The ability of a substance or agent to produce or provoke cancer.

Acute ecotoxicity: Adverse effect on ecosystems and/or the organisms within the ecosystem within a short period of time after exposure to a chemical.

Chronic ecotoxicity: Adverse effects to an ecosystem and/or the organisms within the ecosystem following exposure to a chemical during a substantial fraction of the ecosystem's or organism's lifespan.

Accumulation: The action or process of accumulating within biological tissues.

Persistence: Continued presence of a chemical or its effects in the environment after source or cause has stopped.

3.4.6 Health and safety data for relevant substances

The data for health and safety are extensive and this report only includes references to the databases. Most data can be found on the site of the International Programme on Chemical Safety (IPCS) (www.inchem.org), a collaborative venture of the World Health organization (WHO), the United Nations Environment Programme (UNEP) and the International Labour Organization

(ILO). The IPCS site refers to the ICSCs, CICADs, and EHCs. The International Chemical Safety Cards (ICSCs) (www.inchem.org/pages/icsc.html) provide a structured overview of the data for most of the substances under consideration. The Concise International Chemical Assessment Documents (CICADs) (www.inchem.org/pages/cicads.html) provide extensive data for a very limited number of substances. They are similar to the Environmental Health Criteria Monographs (EHC) (www.inchem.org/pages/ehc.html) which provide internationally accepted reviews on the effects of chemicals or combinations of chemicals on human health and the environment.

Additional data and substances can be found in the databases of the IPCS INTOX Programme, the US EPA, the US National Institute for Occupational Safety and Health (NIOSH), the University of Oxford Physical and Theoretical Chemistry Laboratory, the Programme for Alternative Fluorocarbon Toxicity Testing (www.afeas.org/paft/) and documents from ISO Technical Committees TC 86 "Refrigeration and air conditioning" and ISO TC 21 "Equipment for fire protection and fire fighting". If the data are not available from these sources, then national standards or the material safety data sheet from the supplier can be used as the source of information. Care is needed when using material safety data sheets from suppliers, as these data are not always peer reviewed. The most recent peer-reviewed data agreed at an international level (IPCS, PAFT or ISO) should be used in preference to other data.

The information required for health and safety considerations depend on the subsector and application involved. For example, the data required for refrigeration and air conditioning are different from that for fire protection and medical aerosols. Even within a sector, regional differences exist for detailed data. Each sector shall use the appropriate data valid for it to perform the risk assessment and management with respect to health and safety. For refrigeration and air conditioning an ISO work item has been approved to unify the data and resolve the regional differences (ISO TC 86/SC8/WG5). For fire protection this is handled by ISO TC 21.

3.5 Assessing climate and environmental impacts

This chapter describes approaches in which the environmental comparisons are made systematically using standardized procedures and factors. They are most suitably used for making comparisons between individual installations or items of equipment and do not provide 'generic' information. There is a hierarchy among the system-based approaches, which depends on the scope of treatment, but they all seek to apply data in the same rigorous manner. In every case, care should be taken to examine and clearly define the scope of the analysis, taking into account the requirements of those who commissioned the study.

3.5.1 Environmental impact categories and respective indicators including approaches for their ranking

A rational choice of systems, such as heating and cooling, to provide for societal needs should include an assessment of their environmental impact so that excessive demands on the environment can be identified and avoided. Environmental impact depends as much on the quantity of the material emitted as it does on the material's properties. Climate change and ozone depletion are clearly prioritized in this report. Within another framework, other impact categories such as energy-related acidification or resource depletion could be emphasized. An exhaustive list of potential impact parameters or a definition of the process of life cycle assessment fall outside of the scope of this report. However, the principal environmental impacts that may be considered for systems using HFCs, PFCs and other replacements for ozone-depleting substances are:

Climate Change The radiative effects of CFCs and their alternatives on climate is discussed in detail in Chapter 2 and, for the purposes of comparisons between climate impacts, the most important parameter is *global-warming potential*. This is a conversion factor that relates the climatic impact from an emission of particular greenhouse gas to that of an equivalent amount of emissions of carbon dioxide. It is calculated by integrating the radiative forcing from an emission of one kilogram of the greenhouse gas over a fixed time period (the *integration time horizon, ITH*) and comparing it to the same integral for a kilogram of carbon dioxide; units are (kg CO_2 equivalent)(kg emission)$^{-1}$. Commonly quoted integration time horizons are 20, 100 and 500 years with impacts beyond each ITH being ignored (see Table 2.1). The calculation has to be performed in this way because the reference gas, carbon dioxide, has a very long environmental lifetime; for example its impact up to 20 years is only 9% of that up to 500 years (IPCC, 1996a). The standard values for the emissions accounting required by the Kyoto Protocol are those in the Second Assessment Report of the IPCC (IPCC, 1996a) at the 100-year time horizon. The 20-year time scale does not meet the time criterion for judging sustainability; focusing on 20 years would ignore most of the effect on future generations (WCED, 1987). GWPs from the Second Assessment Report at the 100-year time horizon represent the standard for judging national performance. For the purpose of system comparisons the most recent IPCC GWPs could be used, for example, as presented earlier in this report. However, it should be noted that GWPs are parameters constructed to enable the ranking of emissions of greenhouse gases and do not reflect absolute environmental impact in the same way as, for example, the calculated future radiative forcing described in Chapter 2.

Ozone depletion gases that contain reactive halogens (chlorine, bromine and iodine) and are sufficiently unreactive to be transported to the stratosphere, can cause the halogen concentration in the ozone layer to rise. They are therefore *ozone-depleting substances*. For any given gas the efficiency of ozone depletion depends on the extent to which material released at ground level is transported into the stratosphere, how much halogen each molecule carries and the potency of that halogen for ozone depletion, and how the gas decomposes in the stratosphere and hence how much of its halogen content can affect the ozone layer. These factors are combined in mathematical models of the atmosphere to give relative *ozone depletion potentials (ODPs)* based on a scale where the ODP of CFC-11 (CCl_3F) is unity (Daniel *et al*., 1995; Albritton *et al*., 1999); values important for Life Cycle Assessments are shown in Table 1.1.

Acidification: The two groups principally involved in acidification are sulphur and nitrogen compounds and, with the exception of ammonia, neither the ODS nor their substitutes have a direct effect in this category. However, energy-related emissions can exhibit significant acidification potential, and degradation products of substances such as HF or HCl could have considerable acidification potential. Indicators for potential acid deposition onto the soil and in water have been developed with hydrogen ions as the reference substance. These factors permit computation of a single index for potential acidification (in grams of hydrogen ions[5] per functional unit of product), which represents the quantity of hydrogen ion emissions with the same potential acidifying effect:

$$\text{acidification index} = \sum i\ mi \times APi \qquad (3.5)$$

Where:
mi is the mass (in grams) of flow *i*, and
APi are the millimoles of hydrogen ions with the same potential acidifying effect as one gram of flow i, as listed in Table 3.8.

However, the acidification index may not be representative of the actual environmental impact, as this will depend on the susceptibility of the receiving systems (soil and water, in this case).

Photo-oxidant formation: The relative potencies of compounds in atmospheric oxidation reactions are characterized by their photochemical ozone creation potentials (POCP), on a scale where ethene is 100 (Derwent *et al*., 1998). The hydrocarbon substitutes for ODSs have POCPs ranging from 30 to 60 but HFCs and PFCs are not implicated in any significant photo-oxidant formation (Albritton *et al*., 1989) and are among the lowest priority category for volatile organic compound regulation (UN-ECE, 1991).

Resource depletion: The production of all of the chemicals considered in this report will deplete resources and the extent of this should become apparent in a Life Cycle Assessment. For example, an important consideration for fluorinated gases is the extraction of fluorspar mineral, as most of this is destined for the manufacture of fluorochemicals (Miller, 1999).

Eutrophication is the addition of mineral nutrients to soil or water. In both media, the addition of large quantities of mineral nutrients (such as ammonium, nitrate and phosphate ions) results in generally undesirable shifts in the number of species in ecosystems and a reduction in ecological diversity. In water it tends to increase algal growth, which can cause a depletion in oxygen and therefore the death of species such as fish.

Table 3.8. Acidification-potential characterization factors (Alternatively, in the literature sulphuric oxides are often used as reference).

Flow (i)	***AP_i (hydrogen-ion equivalents)***
Ammonia (NH_3)	95.49
Hydrogen chloride (HCl)	44.70
Hydrogen cyanide (HCN)	60.40
Hydrogen fluoride (HF)	81.26
Hydrogen sulphide (H_2S)	95.90
Nitrogen oxides (NO_x as NO_2)	40.04
Sulphur oxides (SO_x as SO_2)	50.79
Sulphuric acid (H_2SO_4)	33.30

Source: Lippiatt, 2002

Characterization factors for potential eutrophication have been developed, in a similar vein to those for the global-warming potential, with nitrogen as the reference substance. These factors permit the computation of separate indices for the potential eutrophication of soil and water (in grams of nitrogen per functional unit of product), which represent the quantity of nitrogen with the same potential nutrifying effect:

$$\text{eutrophication index (to water)} = \sum i\ mi \times EPi \qquad (3.6)$$

Where:
mi is the mass (in grams) of inventory flow *i*, to water, and
EPi are the grams of nitrogen with the same potential nutrifying effect as one gram of inventory flow i, as listed in Table 3.9.

The calculation for soil eutrophication is similar but, for both soil and water the actual impact will vary, dependent on the ability of the local environment to cope with an additional stress of this sort, as was the case for acidification.

Ecotoxicity is the introduction of a compound that is persistent, toxic and can accumulate in the biosphere (commonly shortened to PTB). All three attributes are required for environmental releases to accumulate to the point at which there is a toxic response. No such compounds are known to be directly associated with the production and use of any of the fluorocarbons considered in this report. An in-depth discussion of ecotoxicity issues can be found in Hauschild and Wenzel (1998), Heijungs (1992) and Goedkoop (1995).

3.5.2 System-based approaches

In these approaches the environmental comparisons are made systematically using standardized procedures and factors. They

[5] The hydrogen release potentials are criticized by some authors. They have proposed alternative factors based on UN-ECE-LRTAP models. See www.scientificjournals.com/sj/lca/pdf/aId/6924.

Table 3.9. Eutrophication Potential Characterization Factors. (Alternatively, in the literature PO4+ is often used as a reference).

Flow (i)	*EPi (nitrogen-equivalents)*
Ammonia (NH_3)	0.12
Nitrogen Oxides (NOx as NO_2)	0.04
Nitrous Oxide (N_2O)	0.09
Phosphorus to air (P)	1.12

are best used for making comparisons between individual installations or items of equipment and do not provide 'generic' information. There is a hierarchy among the system-based approaches, which depends on the scope of treatment, but they all seek to apply data in the same rigorous manner. In every case, the scope of the analysis should be clearly examined and defined, taking into account the requirements of those who commissioned the study.

Life Cycle Assessment (LCA) is clearly the most comprehensive and formal approach to assessing and comparing the environmental impacts of technologies. The methodology for LCAs has been developed and formalized in the ISO 14040 series of international standards. On the other hand, TEWI (Total Equivalent Warming Impact) has the most limited scope, but has been applied most widely for the technologies within the remit of this report. It addresses the climatic impact of equipment operation and the disposal of operating fluids at end-of-life but, although it may be appropriate for most of the common systems, it does not consider the energy embodied in the fluid or equipment. This energy may be important in some cases and this consideration has led to the concept of LCCP (Life Cycle Climate Performance).

In LCCP a more complete climatic impact of the fluid is calculated and includes the impacts from its manufacture, the impacts from operating and servicing the system and finally those associated with disposal of the fluid at the system's end of useful life. However, both TEWI and LCCP consider just the climatic impact; this is reasonable for cases where the predominant environmental impact is on climate. Life cycle assessment (LCA) is the broadest-based approach and this includes the environmental impacts of other inputs and outputs to the system, in addition to those associated with energy.

LCCP can be seen as a submethod of LCA and TEWI as a submethod of LCCP. To a large extent the approach chosen will depend on the context. If the information required is the relative climate impacts of a number of alternative approaches for achieving a societal good, then TEWI or LCCP are likely to provide adequate information. However this will ignore all other environmental impacts that are addressed in LCA, assuming that these will be similar for the alternative technologies. Although the three approaches differ in their scope, all of data should be derived and all of the analyses performed with the same rigour.

3.5.2.1 Total equivalent warming impact (TEWI)

Arguably the largest environmental impact from many refrigeration and air-conditioning applications arises from their energy consumption and emissions during their operation. Similarly, the energy saved by thermal insulating foam is the principal offset for any effect due to fluid emissions. In order to help quantify these effects, TEWI sets out to standardize the calculation of climate-change impact in terms of emissions over the service life of the equipment, including emissions arising from the disposal of the fluids it contains. The units of TEWI are mass of CO_2 equivalent.

TEWI using generic or default data.

The analysis is performed by calculating the direct emissions of the fluids contained in each system from leakage during operation over its entire service lifetime. This includes servicing and the system's eventual decommissioning and disposal. In this context, the system does not cover the full life cycle (ISO, 1997) but includes the operation, decommissioning and disposal of the application.

The total mass emission of each greenhouse-gas component is converted to CO_2-equivalent emissions using GWP (see discussion in Section 3.5.1) as the conversion factor (see Table 2.1). These figures are then added to the emissions of actual carbon dioxide arising from the energy used during operation (see 3.2.2.3) to give a TEWI value for the lifetime of the equipment. Examples of 'equipment' are a refrigeration or air-conditioning system, or a building (particularly if it is insulated). There is often a combination of energy-consuming and energy-conserving parts, and different direct releases of greenhouse gases. Typically:

$$TEWI_S = \sum OR_i \text{ x } GWP_i + \sum DR_i \text{ x } GWP_i + E_I \qquad (3.7)$$

Where:

- $TEWI_S$ is the total equivalent warming impact from system S (for example, a particular refrigeration system or building installation) the units of which are mass of CO_2 equivalent;
- OR_i is the operational release of each greenhouse gas i (the mass total of the releases of each gas during the system's operating lifetime);
- GWP_i is the global-warming potential of greenhouse gas i (at the 100-year integration time horizon, as discussed below);

DR_i is the total mass of each greenhouse gas *i* released when the system is decommissioned, and

E_I is the indirect emission of carbon dioxide resulting from the energy used to operate the system (for its whole lifetime), already discussed in Section 3.2.1.3 and calculated according to Equation 3.2, above.

While this is apparently an absolute value, it can carry a high uncertainty associated with the assumptions and factors used in the calculation. TEWI is most effectively used to compare alternative ways of performing a service, where the same assumptions apply to all of the alternatives and the effect of these on relative ranking is minimized. A TEWI value calculated for one system using one methodology (i.e. set of assumptions, equations, procedures and source data) is not comparable with a TEWI value calculated for another system using another methodology. Then a comparison of TEWI is meaningless.

Depending on the quantity of information available and the needs of the study, there are several levels of complexity in the application of TEWI. At the simplest level, a default emission function could be used for the fluid release together with calculated energy requirements and regional carbon dioxide intensity. Default emission functions have been developed by AFEAS to calculate global emissions from refrigeration and closed-cell (insulating) foams (AFEAS, 2003). One feature of these functions is that all of the substance used is eventually released (in some cases after many years service) and this can have a profound effect on the application's impact.

In this case, the quantity released is equal to the amount originally charged into the system, plus any amount added during the system's period of service:

$$OR_i + DR_i = C_i + QA_i \qquad (3.8)$$

Where OR_i and DR_i are the operational and decommissioning releases of substance *i* as described above;
C_i is the mass of *i* originally charged into the system, and
QA_i is the mass of *i* added into the system during its service life.

For hermetic refrigeration systems (such as domestic refrigerators and window air conditioners), units are rarely, if ever, serviced and therefore QA_i is set at zero because of its insignificance. Yet for systems which require frequent servicing, such as mobile air conditioning, that default condition is not appropriate and a value for QA_i could be derived by analogy from the operation of similar systems.

Energy (either as power required to operate the system or the energy saved by thermal insulation) can be calculated using standard engineering methods. In many cases, electricity is used to power the equipment and this will have been produced by technologies that vary between countries and regions, with large differences in the fossil fuels used as primary sources (for more information see Section 3.2.1.3). Table 3.5 lists some regional and national carbon dioxide intensities for electricity. Such a calculation is only suitable for showing major differences (say within a factor of two) due to the extensive use of default factors. Nevertheless, it is useful for identifying the more important areas of the calculation that would repay further refinement (Fischer *et al*., 1991 and 1992; McCulloch, 1992 and 1994a). Uncertainties can be significantly reduced by using appropriate specific data.

GWP and integration time horizon

For the conversion of other greenhouse-gas emissions into their CO_2-equivalents, GWPs at the 100-year integration time horizon are usually used and the source of the GWP values must be clearly stated. For example, TEWI analyses are now usually performed using the most recent GWP values published by the IPCC, even though this is not the normative standard. To ensure that the results are as portable as possible and to facilitate intercomparisons, the standard values from the Second Assessment Report of the IPCC (IPCC, 1996a) as used in the emissions accounting reported under the Kyoto Protocol and UNFCCC, have frequently been used in existing TEWI analyses.

TEWI using specific data

The next level of complexity goes beyond the use of generic data. It requires real emission patterns obtained from field trials and operating experience and, preferably, the range of values obtained from such studies should be indicated and used in a sensitivity analysis (Fischer *et al*., 1994; ADL, 1994 and 2002; Sand *et al*., 1997; IPCC/TEAP, 1999). As the disposal of the fluid can have a significant impact, it is important to incorporate the real emissions on disposal. If the systems under consideration do not yet exist, the methods for calculating emissions patterns should have been verified against real operating systems.

Similarly, the actual energy consumption based on trials should be used in the more thorough analysis, together with the carbon dioxide intensity of the energy that would actually be used in the system. Many systems are powered electrically and therefore the procedures already discussed in Section 3.2.1.3 should be applied so as to facilitate comparisons between similar systems operated in different countries.

As in many cases electrical energy is the most important energy carrier, the sum of the other fuel usages and intensities can be neglected so that Equation 3.2 becomes:

$$E_I = Q_E \times I_E \qquad (3.9)$$

Where
E_I is the total indirect lifetime emission of carbon dioxide from the energy used to operate the system;
Q_E is the total lifetime use of electricity, and
I_E is the average carbon dioxide intensity of national electricity production (from Table 3.5)[6].

Uncertainty

When most of the impact arises from fluid emissions, the criterion for significance is set by the uncertainty of the GWP values and this is typically 35% (IPCC, 1996a). Where the impact is a combination of fluids and CO_2 from energy, the more common case, the total uncertainty should be assessed. A rigorous uncertainty analysis may not be meaningful in all cases or might not possible due to the poorly quantified uncertainties of emission factors, emissions from the energy supply systems, specific energy consumption and the like. However, the sensitivity of uncertainty in the data is valuable because the effort required to gather the information needed for increasingly detailed calculations, will only be repaid if these show significant differences.

Uses

TEWI is particularly valuable in making choices about alternative ways of performing a function in a 'new' situation but it also can be used to minimize climate impact in existing operations by providing information on the relative importance of sources, so that remedial actions can be prioritized. This is, however, methodologically restricted to those cases in which the original and alternative technologies remain reasonably similar throughout their life cycles.

A standard method of calculation which includes the concepts and arithmetic described here has been developed for refrigeration and air-conditioning systems, and the principles of this may be applied to other systems (BRA, 1996, consistent with EN378, 2000). TEWI can also be used to optimize the climate performance of existing installations and methods of working (McCulloch, 1995a; DETR, 1999). A particularly valuable application is in the construction or refurbishment of buildings, where TEWI can be used to facilitate the choice between different forms of insulation, heating and cooling. The affect of the design on both the TEWI and cost can be investigated, and significant greenhouse-gas emissions abated (DETR, 1999). The interaction between TEWI and cost is particularly useful when additional equipment is required to achieve an acceptable level of protection. For example, the cost of that safety equipment could have been invested in efficiency improvements (ADL, 2002; Hwang *et al*., 2004).

If sufficient information is available, TEWI can also be used to examine the climate and cost incentives of targeting operations at particular periods of the day or year when the carbon dioxide intensity of electrical power is lower (Beggs, 1996).

3.5.2.2 Life cycle climate performance (LCCP)

Like TEWI, this form of analysis concentrates on the greenhouse-gas emissions from direct emissions of operating fluids together with the energy-related CO_2 but, it also considers the fugitive emissions arising during the manufacture of the operating fluids and the CO_2 associated with their embodied energy. Like TEWI, LCCP is most effective when applied to individual installations, and a 'generic' LCCP will only be representative only if the data used to calculate it are representative of the types of installation being examined.

A comprehensive study has been made of representative LCCPs for alternative technologies in the areas of domestic refrigeration, automobile air conditioning, unitary air conditioning, large chillers, commercial refrigeration, foam building insulation, solvents, aerosols (including medical aerosols) and fire protection (ADL, 2002). The results were very similar to those of the TEWI analyses (see particularly Sand *et al.* (1997)). For example, the LCCP of domestic refrigerators was dominated by their energy use and there was no clear difference between the refrigerant fluids or blowing agents used in insulating foams. However the end-of-life disposal method has a significant impact on the LCCP (Johnson, 2003). As long as the disposal of all of the systems was treated in the same way, automobile air conditioning was most heavily influenced by the conditions under which it was operated (the climatic and social conditions of different geographical areas). Thus the highest LCCP values arose for vehicles in the southern USA, and this value was higher still if the fluid chosen did not allow for efficient operation (ADL, 2002).

LCCP is a useful addition to the TEWI methodology, even though in many cases the influence of fugitive emissions and embodied energy (which account for most of the difference between TEWI and LCCP results) can be small compared to the lifetime impact of using the system.

$$LCCP_S = TEWI_S + \sum OR_i \times (EE_i + FE_i) + \sum DR_i \times (EE_i + FE_i) \quad (3.10)$$

Where:

$LCCP_S$ is the system Life Cycle Climate Performance;

$TEWI_S$ is the system TEWI, as defined by Equation 3.5.1 above;

OR_i and DR_i are, respectively, the quantities of fluid i released from the system during operation and at decommissioning;

EE_i is the embodied energy of material i (the specific energy used during the manufacture of unit mass, expressed as CO_2 equivalent), and

FE_i is the sum of fugitive emissions of other greenhouse gases emitted during the manufacture of unit mass of i (expressed as their equivalent CO_2 mass), so that:

$$EE_i = \sum (EE_j \times I_{Fj}) \quad (3.11)$$

for j sources of energy used during the production of material i, each with a carbon dioxide intensity of I_{Fj} (see also Equation 3.2), and:

[6] The differing practice of using the carbon intensity of the most expensive fuel in an attempt to show the situation for an additional demand in a deregulated energy market, could be misleading. This carries unwarranted assumptions: the demand may not be additional, even if the system represents a new load. It is most probable that the effect of the new system on the energy balance would be, at least in part, to replace demand from elsewhere. And even if demand is additional, it may not result in the most expensive energy being used. That would depend on the daily, weekly and seasonal demand pattern, which is beyond the scope of this level of TEWI analysis.

$$FE_i = \sum (FE_j \times GWP_j) \quad (3.12)$$

for j greenhouse gases emitted during the production of material i, each with a global-warming potential at 100 years of GWP_j.

A comparison of Equations 3.7, 3.10, 3.11 and 3.12 shows that the difference between LCCP and TEWI is that the GWP of each greenhouse-gas component is augmented by the embodied energy and fugitive emissions of that component. However, the effect of these is now generally quite small as in much of the world the practice is to minimize or destroy process emissions (compare Section 3.2.1.1).

A relatively straightforward application for TEWI and LCCP analyses is the study of emissions attributable to a household refrigerator. In this case, either the refrigerant choice or the blowing agent choice may be studied, or both. Table 3.10 gives a summary of the items that would typically be considered in such studies.

3.5.2.3 Life Cycle Assessment (LCA)

LCA is a technique for assessing the environmental aspects of a means of accomplishing a function required by society (a 'product or service system' in LCA terminology) and their impacts. A life cycle assessment involves compiling an inventory of relevant inputs and outputs of the system itself and of the systems that are involved in those inputs and outputs (Life Cycle Inventory Analysis). The potential environmental impacts of these inputs and outputs are then evaluated. At each stage it is important to interpret the results in relation to the objectives of the assessment (ISO, 1997). Only an assessment which covers the full life cycle of the product system can be described as an 'LCA'. The methodology is also applicable to other forms of assessment, such as TEWI described above, provided that the scope of the assessment and its result are clearly defined. So whereas LCA studies describe the environmental impacts of product systems from raw material acquisition to final disposal, studies that are conducted to the same rigorous standards for

Table 3.10. Items considered in TEWI and LCCP studies for a refrigerator (Johnson, 2003).

	Considered in	
	TEWI	**LCCP**
Refrigerant		
Emissions of refrigerant:		
• During manufacturing of the refrigerant		X
• Fugitive emissions at the refrigerator factory	X	X
• Emissions during the life of the product (leaks and servicing)	X	X
• Emissions at the time of disposal of the product	X	X
Emissions of CO_2 due to energy consumption:		
• During manufacturing of the refrigerant		X
• During transportation of the refrigerant		X
Blowing agent		
Emissions of blowing agent:		
• During manufacturing of the blowing agent		X
• At the refrigerator factory	X	X
Emissions of blowing agent from the foam:		
• During the life of the product	X	X
• At the time of disposal of the product	X	X
• After disposal of the product	X	X
Emissions of CO_2 due to energy consumption:		
• During manufacturing of the blowing agent		X
• During transportation of the blowing agent		X
The refrigerator		
Emissions of CO_2 due to energy consumption related to the product:		
• During manufacturing of components		X*
• During assembly of the refrigerator		X*
• During transportation of the refrigerator		X*
• By the refrigerator during its useful life	X	X
• During transportation of the refrigerator for disposal		X*
• During disposal of the refrigerator (usually shredding)		X*

* These items are relatively small in comparison with emissions related to the power consumed by the refrigerator and those related to emission of the blowing agent, and are independent of the refrigerant and blowing agent. They may therefore be neglected in some LCCP studies.

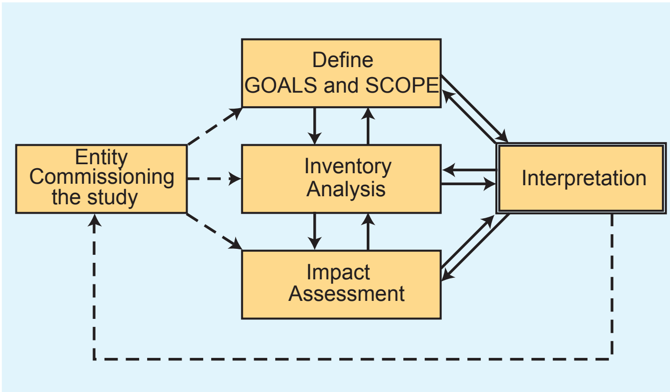

Figure 3.6. Outline phases of a Life Cycle Assessment and interactions with the commissioning entity.

subdivisions of the product chain (for example up to the sale of a unit to a customer) or subdivisions of the environmental impact (for example LCCP and TEWI) are just as valid, and may better meet the requirements of those commissioning the study. Indeed as the use phase usually dominates the environmental impact of the CFC substitutes, the LCA will be application-specific. However, attempts to provide 'generic' LCA results can help to identify the most relevant life-cycle stages and impact categories. These attempts will also tend to be tests of the extent to which the assumptions made about this use phase actually match the real performance of the application.
Figure 3.6 shows the steps in the general methodology.

For any given analysis it is essential that the objective is clearly defined. This should include the application, reasons for the study and the intended recipients of the results. To meet this objective, the scope of the study needs to specify the performance characteristics of the product and to define a 'functional unit' that will be used to quantify these characteristics (ISO, 1997 and 1998). This is a particularly important step and is best illustrated with examples:

Once a functional unit that is practical and meets the needs of those commissioning the assessment has been defined, a reference flow can be established from which all of the ancillary inputs and outputs may be calculated. For example, in a cold store this could be the annual throughput of foodstuff from which the number of receipts and deliveries, the energy load, and so forth can be estimated. In any LCA it is essential that the system boundaries are clearly and unambiguously defined. This includes not only the boundaries of the primary physical system under assessment (in this example the cold store) but also the extent to which inputs and outputs will be traced back to elementary flows (material drawn from or placed into the environment). The documentation for the decisions on system boundaries should be sufficient to judge whether or not more detailed examination is desirable and to permit subsequent changes to the assessment if new information becomes available.

Once the system has been defined, it should then be described in terms of its unit processes and their interrelationships. Each of these unit processes has its own set of inputs and outputs, enabling a matrix of flows, based on the reference flow, to be constructed. This constitutes the Life Cycle Inventory. In the subsequent stages of LCA, the environmental impacts of the inputs and outputs identified in the inventory are assessed. For the materials addressed in this report, the most obvious impact categories are climate change and ozone depletion but some or all of the additional categories described in 3.5.1 above may be important (ISO, 2000a and 2000b). The end product is a description of the environmental impacts of a defined product system in terms of the effects on the most appropriate individual categories, together with an indication of how significant that impact is for each category. There is no scientific basis for reducing LCA results to a single overall score or number (ISO, 1997) and, similarly, there is little justification for closely ranking impacts (although it is worth noting when one impact, such as that on climate change, clearly outweighs the rest). A data documentation format for Life Cycle Assessments has been developed (ISO, 2002) to facilitate common input. Data collection formats have also been developed for specific applications, such as motor vehicle manufacture (Finkbeiner *et al*., 2003) and plastics (O'Neill, 2003) and, similarly, large consistent databases are now sold (for example at www.ecoinvent.ch/).

It is difficult to characterize the uncertainty in LCA; there are a large number of variables with varying degrees of autocorrelation and for which formal uncertainty analyses may not exist. However, it should be possible to perform sensitivity analyses with comparatively little effort so as to provide a commentary on the significance of the impacts determined in the assessment (Ross *et al.,* 2002). The requirements for data quality assessment are described in ISO (1997, 1998, 2000b).

In order to facilitate complete LCA studies involving refrigerants and foam blowing agents, several studies have been performed to characterize the environmental impacts of fluid manufacture. The general conclusion was that the impact from producing the fluids was small compared to that arising from their use during service and their eventual disposal (Banks *et al*., 1998; Campbell and McCulloch, 1998; McCulloch and Campbell, 1998; McCulloch and Lindley, 2003). The most significant contribution to the impact for producing fluids comes from material, such as other fluorocarbons, released during the manufacturing process and there is a wide variation in the values used. The highest values were calculated by Banks *et al.* (1998) who used maximum permitted emissions rather than real values. The other studies used actual process records so that the amount of material released was not only lower but also decreased substantially in recent years as the treatment of vent gases to avoid their release to the atmosphere became more commonplace, particularly in the new plants to manufacture HFCs (Campbell and McCulloch, 1998; McCulloch and Campbell, 1998; McCulloch and Lindley, 2003).

As for studies of complete systems, Yanagitani and Kawahari (2000) confirmed that for air-conditioning systems the largest source of environmental impact arose from energy use, but that proper waste management at end-of-life could significantly reduce the impact. The predominant influence of energy production on the impact on global warming, acidification, aquatic ecotoxicity, photochemical ozone creation, terrestrial toxicity and the proliferation of radionuclides was demonstrated by Frischknecht (1999) in LCA studies of generic heat pumps, building air conditioning, and industrial and commercial refrigeration.

3.5.2.4 Other system-based approaches

Environmental burden
Environmental burden is a method for assessing the environmental impact of a production facility. Mass emissions of individual compounds released from the site are multiplied by a 'potency' that characterizes the impact of the compound on a particular environmental end-point (for example ozone depletion or global warming). The sum of these values in each impact category is the environmental burden of the facility (Allen *et al.,* 1996). The resulting site-specific review of environmental impact can be used in environmental management (as described in ISO 14001).

Eco-efficiency
This combines Life Cycle Assessment of similar products or processes with a total cost determination of each alternative. Economic and ecological data are plotted on an x/y graph, with costs shown on the horizontal axis and the environmental impact on the vertical axis. The graph reveals the eco-efficiency of a product or process compared to other products or processes, with alternatives that have high cost and high impact occupying the upper right-hand quadrant. Similarly, those with low impact and low-cost occupy the lower left-hand quadrant, close to the origin. (BASF, 2003). However, such analyses demand a great deal of accurate data.

3.6 Regional dimensions

The use of fluorocarbons is specific to certain technical sectors. The technology selection in these sectors, their customers and product developments are influenced by a number of factors, which are of a local, national or regional nature (e.g. EU regulation (COM(2003)0492), under preparation). In addition to technical requirements, those factors can also include cost, environmental considerations, legal requirements, health and safety issues, energy inputs and costs and market characteristics. Therefore prescriptions on how to arrive at these decisions are not possible, as each country, and each enterprise within it, must make its own decision. Against this background, this section presents some of the more general characteristics and considerations that will influence the choice of technology at both the national and enterprise levels.

This section also highlights some of the regional differences that influence technology choice. For these purposes, countries are considered in groupings recognized under the Montreal Protocol, namely:

- Latin America and the Caribbean;
- Africa and the Indian Ocean;
- Asia/Pacific region;
- Countries with economies in transition; and
- Developed countries.

Table 3.11 gives an overview of regional variations in key methodological issues.

3.6.1 Sector characteristics

3.6.1.1 Refrigeration and air conditioning
Growth in the demand for refrigeration has paralleled the demand for food preservation, processing, freezing, storage, transport and display, as well as final storage in homes. The more centralized food production becomes, and thus further removed from the consumer, the greater the amount of refrigeration. Consequently, societies with a more complex food supply structure and countries with a higher urban population will have a higher demand for refrigeration than countries supplying food from more local sources.

Large air-conditioning systems with capacities of about 1 MW cooling capacity upwards, are used in most of the large commercial buildings, hospitals and hotels around the globe, irrespective of the local climate (UNEP, 2003c). The occurrence of such systems roughly matches the occurrence of the type of buildings described. Smaller air-conditioning systems are largely desired in countries with warm climates (UNEP, 2003c), but there is an increasing market for these in areas with a more moderate climate, for example Central and Northern Europe. Therefore, the influencing factors for the spread of such systems are the occurrence of high ambient temperatures, and high humidity, as well as available income.

There is an almost universal preference for mobile air conditioning, even in colder climates. The only limiting factor is the cost of the system, which typically has to be covered when purchasing the vehicle. Certain types of systems – refrigerators, unitary air conditioning products and water chillers – have universal usage characteristics and can therefore be manufactured in centralized facilities. This simplifies quality control and reduces the likelihood of leaks, and thus the need for service. Nevertheless, since high ambient temperatures create an increased demand for servicing due to higher mechanical stress on the systems and longer periods of operation, and considering that most repairs currently lead to emissions of the refrigerant, hot climates tend to have higher levels of refrigerant emissions than cooler climates. In other sectors, for example most commercial refrigeration systems, the installations are too custom- or location-specific to be manufactured in a centralized facility, although research is underway to change this (UNEP, 2003c).

Maintenance philosophies which encourage preventive maintenance of refrigeration equipment, have lower emissions and maintain a stable energy-efficiency performance. The decision to have preventive maintenance or to request service

Table 3.11. Overview of regions and specific methodological dimensions.

Region **Dimension**	**Latin America and Caribbean**	**Africa and Indian Ocean**	**Asia-Pacific**	**Countries with economies in transition**	**Developed countries**
3.2 Key Technical Performance Indicators					
3.2.1 lifetime perspectives	No specific differences with the exception that the more expensive equipment generally has a longer lifetime. Such expensive equipment is sold more in developed countries, where standards are higher, and enforced.				
3.2.2 Fluid emission rates	Some care during fluid production. Frequent maintenance requirement due to high ambient temperature, yielding more fluid emissions. Poor care for fluid emissions at service and disposal, but this is being addressed under initiatives funded by the Multilateral Fund of the Montreal Protocol.	Frequent maintenance requirement due to high ambient temperature, yielding more fluid emissions. Poor care for fluid emissions at service and disposal, but this is being addressed under initiatives funded by the Multilateral Fund of the Montreal Protocol.	Some care during fluid production. Poor care for fluid emissions at service and disposal, but this is being addressed under initiatives funded by the Multilateral Fund of the Montreal Protocol.		Significant care during fluid production. Significant care during servicing and some during disposal of equipment.
3.2.3 Energy aspects	The energy aspect is not the driving factor when buying new equipment and material. Main factor is initial cost.				High concern with use of highly-efficient equipment.
	Significant share (72%)[1] of renewable electricity. Some concern about energy efficiency.	Moderate share (19%)1 of renewable electricity.	Significant use of fossil fuel (79%)[1] for electricity. Some concern about energy efficiency.	Average use (63%)[1] of fossil fuel for electricity	Average use (60%)[1] of fossil fuels for electricity.
3.3 Categories Of Cost					
3.3.2 Direct engineering and financial cost	Always considered. Focus on manufacturing, mostly assembly.		Always considered. Some R&D and component manufacturing.	Always considered Some component manufacturing.	Includes liability provision. Significant R&D and component manufacturing.
3.3.2.1 The time dimension in cost 3.3.2.2 Discounting	High interest rate.	High interest rate.	Average interest rate.	Average interest rate.	Low interest rate.
3.3.3 Investment cycle and Sector Inertia	Shortage of capital. Large inertia due to unavailability of resources for transition away from HCFC.		High economic development/ modest inertia. Little emphasis on transition away from HCFC.	Shortage of capital/large inertia. Transition away from HCFC according to Montreal Protocol schedule.	Strong pressure from legislation/low inertia.

Table 3.11. Continued

Region / Dimension	Latin America and Caribbean	Africa and Indian Ocean	Asia-Pacific	Countries with economies in transition	Developed countries
3.3.4 Wider costing Methodologies-Concepts	Not accounted.				Modest consideration.
3.3.5 Wider costing methodologies- cost categories	Life Cycle Cost (LCC) generally not considered.				LCC used as a marketing tool.
3.3.6 Economic Key drivers and technology uncertainty	Montreal Protocol Fund; Growing domestic and export markets; Low uncertainty since technology is generally imported; High uncertainty on HCFC future price. Large fluid producer.		Montreal Protocol Fund; Growing equipment market (domestic and export) Medium uncertainty due to fast transition. Large fluid producer.	GEF support for transition based on Montreal Protocol schedule, but some difficulties to achieve targets. Large fluid producer.	Market Leadership; Medium uncertainty due to fast transition.
3.3.7 Other issues	Increasing legislative framework to control trade in ODSs and trade in related technologies under the Montreal Protocol.				National and regional legislation more restrictive than Montreal Protocol.
3.4 Health And Safety Issues					
3.4.1 Health and Safety considerations	Modest concern due to modest liability. Main influence is from the USA.	Modest concern due to modest liability. Mainly influenced by Europe.	Growing concerns in production facilities. Mainly influenced by Europe.	Growing concerns in production facilities. Mainly influenced by Europe.	These two issues are the driving factors in USA and Europe policy design.
3.5 Climate And Environmental Impacts	Modest contribution; Main driver is ozone layer protection.		Significant contribution; Main driver is ozone layer protection.		Large contribution. Europe and Japan are taking a leading role in mitigation.

[1] Assessments based on data from International Energy Agency database, and considers electricity production from fossil and non-fossil (including nuclear) fuels.

only in the case of system failures, is not only dependent on the labour costs but also the business culture and the use-specific importance of uninterrupted delivery of refrigeration capacity. Labour costs, business culture and the value of reliable services are country-specific.

The widespread use of refrigeration and air-conditioning technology, and the accompanying high demand for service and repairs, makes the diffusion of improved techniques important. However, the large number of servicing companies makes it difficult to introduce new maintenance practices and to ensure that these are adhered to (UNEP, 2003c). Through the Montreal Protocol, networks of service technicians have been established in several countries for the diffusion of information within the service sector enterprises, and in some cases there are also mechanisms in place to facilitate a certain maintenance quality. For low-cost, factory-manufactured equipment, such as refrigerators or small- and medium-sized, air-conditioning systems, high labour costs reduce the demand for servicing and instead favour early replacement. Although this results in lower emissions during maintenance, there is the potential of repair-worthy systems being dumped in countries with a lower level of income. This further complicates the situation in poorer countries as ageing refrigeration systems tend to have higher emissions and energy consumptions, and require more frequent repairs (UNEP, 2003c).

Methods of disposal at the end-of-life of the equipment also have implications for the life-cycle GHG emissions of the equipment. (IPCC, 2001b, Chapter 3 Appendix). Given the widespread ownership of refrigeration systems and the high costs associated with recycling, appropriate disposal at end-of-life is at present (2004) more the exception than the rule in most regions. However, several countries have established legislation requiring certain disposal practices, although enforcement is still generally a challenge. For example in Japan, a recent system of CFC coupons compulsorily acquired by car owners when the car reaches end-of-life and are transferred to car dismantlers as they recover the fluid, is not performing well (www.yomiuri.co.jp/newse/20030511wo12.htm). The need for enforcement is further amplified by the fact that users have purchased the equipment many years, if not decades, before the disposal takes place, making data availability and the link between the manufacturer and the user fairly weak.

Customs tariffs have, according to experience gained under the Montreal Protocol, not significantly hindered the spread of new technologies. A further complication is the adherence to different national or regional regulations and standards, which are often mandatory in nature. These might not be compatible with the use of alternative technologies and their characteristics, or might hinder supplies of refrigerants and spare parts. These difficulties can be both substantial and long-lasting, thereby delaying the introduction of new technologies by several years.

In the case of mass-produced refrigeration systems, in particular refrigerators and air-conditioning systems, high labour costs in some regions have made the migration of industrial production an issue. With decreasing freight tariffs, refrigerators are also being increasingly transported over long distances, although differences in local requirements mean that the product is less standardized than air conditioners.

Investment capacities and interest to invest are also significant drivers for technology diffusion, for both manufacturers and consumers. Typically, manufacturers invest in new technology in response to consumers' demands and/or legal requirements[7]. For small manufacturers and technicians in the informal sector, investments are very complicated, especially as there are often few options for obtaining loans in many less-developed countries.

3.6.1.2 Foam sector

During the implementation of the Montreal Protocol, the consumption of CFCs in foam manufacture was largely phased out, and these were replaced by different technologies. In closed-cell rigid insulating foams, hydrocarbons including cyclopentane, n-pentane, isopentane and blends have been widely used in foam subsectors, where energy efficiency, safety and product performance criteria can be met. In flexible foams, CO_2 (water) technology has been successfully introduced. Currently, the most significant uses of HCFCs (developing countries) and HFCs (mostly developed countries) are in rigid insulating foam subsectors, where safety, cost, product performance and energy conservation are important (UNEP-TEAP, 2003).

[7] See for example the EU regulation on Fluorinated Gases under discussion (COM(2003) 0492).

For closed-cell rigid insulating foams, a large portion of the blowing agent remains in the foam until the end of its useful life (UNEP, 2003b). Consequently, the disposal practice (landfill compared with incineration) has a large influence on the direct emissions from a system (i.e., a refrigerator or a building) insulated with foams blown with fluorocarbons. Foam disposal requires collection from a large number of individual users or retrieval from a large quantity of mixed solid waste such as demolished building rubble. This is further complicated by the fact that, in some cases, the foams are integrated with other materials, for example, when used as building material it is adhered to substrates. These factors will make collection a major logistical and legal undertaking, which has not been mastered except in certain subsectors like domestic refrigeration, and even there, only a few countries are implementing such measures (UNEP, 2003b). As most foam products are lightweight compared to their volume, transportation costs prohibit their transportation over long distances, unless the foam is only a small fraction of the final product or system (i.e., a refrigerator). Addition, the movement of foam products, in particular building insulating foams, is further hindered by building construction traditions and building code requirements, which differ significantly between countries.

3.6.1.3 Solvents

The solvent sector is characterized on the one hand by the small scale, open use of solvents and on the other hand by use in industrial processes or closed machines. Both industrial uses and closed machine uses have undergone significant improvements as part of the efforts to reduce the use of ODSs under the Montreal Protocol. A completely different issue is the open use of solvents. For some open uses in medium-size consuming operations, investments might lead to a transition towards closed uses with internal recycling of the solvents. In other uses, in particular cleaning in smaller workshops, the solvent will evaporate into the atmosphere. Low labour costs and, thus, less automated production tend to support the open use of solvents. As in the case of the refrigeration sector, the large number of users in non-homogenous solvent applications makes the spreading of know-how a complex and labour-intensive undertaking (UNEP, 2003d). There are no substantial technical barriers to phasing out ODSs in the solvent sector. Alternatives are available that will meet the needs of all solvent users with very few exceptions. The main barrier to overcoming the obstacles in developing countries is communication and education about suitable alternatives. (UNEP, 2003d).

3.6.1.4 Aerosols/MDIs

Since the beginning of the Montreal Protocol, most aerosol uses of fluorocarbons have been converted to other motive agents, particularly hydrocarbons (UNEP, 2003e). Even so in Japan alone, 1850 tonnes of HFCs were distributed in about 4.5 million cans in 2003. This is a considerable increase compared to the 1050 tonnes distributed in 1995. It is estimated that 80% of these cans are used to blow away dust. The fluid used (HFC-

134a) has a high GWP and measures adopted by the government to replace it with a fluid with a lower GWP (HFC-152a) are only slowly having an effect (www.asahi.com/english/business/TKY200405270126.html). Furthermore, certain critical technical and/or laboratory uses of CFCs remain that are not controlled under the Protocol. For the users of such specialised aerosols the associated costs are less important. In these specific sectors, the introduction of alternatives to fluorocarbons is very knowledge intensive. However, due to the limited number of manufacturers, the number of specialists needed for technology transfer is limited (UNEP, 2003e). National legislation with respect to imports and standards is important because several products, in particular pharmaceuticals, need to adhere to national or regional standards. Most countries require intensive testing of new pharmaceuticals before the lengthy approval process is initiated and this can delay the introduction of new technologies. For all specialized products, manufacturers will often face very significant investments for research and development, testing, licenses and approval. The cost of converting production facilities to utilize alternative technologies could also be high.

3.6.1.5 Fire protection

Fire protection is a knowledge-intensive sector, which only needs a few specialists to service the limited amount of facilities. The diffusion of new technologies can therefore be undertaken with a limited amount of effort. Appropriate servicing of fire protection equipment and, where applicable, the subsequent appropriate disposal and destruction are key elements in the overall climate impact of these applications. The specific nature of this sector provides good opportunities for implementing containment measures for remaining applications, for example the banking of halons under the Montreal Protocol. For the introduction of new technologies, fire protection has a similar characteristic requirement to pharmaceuticals. The safe and efficient use of the agents has to be proven before new technologies can be accepted. This can cause significant delays in technology transfer. The costs of the systems are, within certain limits, secondary for the user because fire protection systems are required and/or essential and form an integral part of the purchase of buildings, military equipment or aircraft.

3.7 Emission projections

HFC and PFC emissions arise from two distinct sources (process emissions and releases when the product is in use (including disposal)) that require different methodologies for accounting historic and current mass emissions or for projecting mass emissions in the future.

Process emissions that occur during chemical production are subject to pollution-control regulations in many countries. These originate from a relatively small number of large facilities and are potentially simple to monitor. For example, there are some thirteen companies throughout the world that produce HCFC-22 and hence could be sources of the HFC-23 byproduct (AFEAS, 2003; EU, 2003). Together with their subsidiaries and associates, and the other independent facilities in a small number of developing countries, these constitute a set of 50 potential emission sites, which are point sources. A standard methodology exists to monitor the release of HFC-23 from these facilities (DEFRA, 2003; IPCC, 2000a) and future emissions will depend on production activity and the extent to which byproducts are abated at the sources.

Emissions arising during use of a fluorocarbon, or on disposal of the system containing it, occur over a much wider geographical area than the point source emissions described above. Furthermore, the losses are spread out over the service lifetime of the system with system-dependent rates of release; for most applications this will result in an emissions pattern that covers several years after the system is charged. Future releases will therefore depend on the release pattern from the current deployment, future changes in the number of systems, how widespread the use of fluids is and the extent to which the fluids are contained during usage and disposal. Methodological guidance is available for monitoring current releases of HFCs and PFCs from refrigeration and air-conditioning systems, foam blowing, aerosols, solvents and fire-fighting applications (IPCC, 2000a) and there is a standard methodological protocol for calculating releases from refrigeration systems (DEFRA, 2003).

Almost all predictions of future emissions are extrapolations of current quantities and trends and, the primary difference in methodology is the extent to which this is based on either:
a) An appreciation of the details of the market for the systems and the way those, and the emission rates of fluids, will change in the future (bottom-up approach)[8], or b) A view of the economy as a whole and the emissions arising from the niches filled by HFCs and PFCs, so that trends are governed by overall economic parameters (top-down approach).

3.7.1 Process emissions

This category includes emissions of HFC-23 from the production of HCFC-22 which, in recent years, has been the largest fluorocarbon contribution to potential climate change. This release of HFC-23 is used to exemplify the requirements for forecasting emissions.

In general, process emissions can be related to process activity:

$$E_i = A_i \times F_i \qquad (3.12)$$

Where:
E_i is the annual emission in year i;
A_i is the activity in that year, and
F_i is a factor relating activity to emissions.

8 This terminology is widely applied but has a variety of meanings. In this part of the report, all predictions based on study of HFC and PFC markets will be called bottom-up. Top-down will be used only for predictions based on macroeconomic parameters.

In the case of HFC-23, A_i is the annual rate of production of HCFC-22 for all uses, whether or not the HCFC-22 is released into the atmosphere or used as feedstock for fluoropolymer manufacture; so that the calculation of future activity will be a projection of both dispersive and feedstock end-uses. The global estimates of the production of HCFC-22 for dispersive use that were made for comparison with atmospheric measurements (McCulloch *et al*., 2003) can be extrapolated in accordance with the provisions of the Montreal Protocol as outlined in Montzka and Fraser (2003). It is important that such estimates include the significant changes in production in the developing world that are evident from UNEP (2003a). The fluoropolymers are products in their own right and have different markets and growth rates from that of HCFC-22, which, in this case, is simply a raw material. These growth parameters will need to be extrapolated separately and explicitly for developed and developing economies in order to calculate a credible total activity.

HFC-23 (trifluoromethane) is formed at the reactor stage of the manufacture of HCFC-22 (chlorodifluoromethane) as a result of over-fluorination. Its formation is dependent upon the conditions used in the manufacturing process and amounts to between 1.5–4.0 % of the quantity of HCFC-22 produced. Its production can be minimized by optimizing process conditions but the most effective means of elimination is destruction by thermal oxidation (Irving and Branscombe, 2002). Thus, the emission factor F_i for HFC-23 lies between zero and 4%. Use of a single value (3%) as the default emission rate (Irving and Branscombe, 2002), although allowed in the methodology for calculating national greenhouse-gas emissions (IPCC, 2000a), is not likely to give a credible forecast. In many cases, actual HFC-23 emission rates are recorded in national greenhouse-gas inventories (UNFCCC, 2003) and these can be used as information on the trends in emission rate (either the absolute rate or the rate relative to HCFC-22 production). It should also be possible to take into consideration national regulations that will affect such emissions in order to generate more robust predictions.

3.7.2 Calculating releases of fluorocarbons during use and disposal from sales data

Models used for extrapolation of emissions need to match historical data, including trends and, at the simplest level this means that the extrapolated data must start from the recorded baseline. Furthermore, the projections need to match the shape of the historical growth (or decline) in the sales from which emissions are calculated.

There is a long record of historic data for audited production for all of the major CFCs, HCFCs and HFCs (AFEAS, 2003). These data are consistent with the aggregated values for CFC and HCFC production and consumption reported under the Montreal Protocol (UNEP, 2002). The annual releases of CFC-11 and CFC-12, HCFC-22 and HFC-134a have been calculated from the audited production and sales (which are reported in categories having similar emission functions), and been shown to be consistent with the atmospheric concentrations observed for these species (McCulloch *et al.,* 2001; 2003). This indicates that the emission functions for these compounds from use in refrigeration, air conditioning, foam blowing, solvent applications and aerosol propulsion are robust. Comparisons between atmospheric concentrations and production or sales can also be used to refine emission functions (Ashford *et al*., 2004).

The primary variables that respond to economic parameters are the activities for the product, which in this case is the use (or sales) of that product in the categories listed above. Emissions are then secondary variables calculated from the deployment in these categories (commonly called the banks) according to models of the time pattern of the extent of emissions. These time patterns may change in response to factors such as legislation (McCulloch *et al.,* 2001).

Consideration of the long-term production databases for a wide range of industrial halocarbons, including CFCs and HCFCs, has shown that the compound growth model can be seriously misleading. It fails to replicate the shape of the demand curve over time for any of the materials examined (McCulloch, 2000). This appears to be because it does not address the changes which occur over the product lifetime. Therefore whereas growth during the early stages of product life may be compound, and hence directly related to an economic parameter such as GDP, it assumes a linear relationship with time when the product becomes more mature and then starts to assume an asymptote at full maturity. As S-curve has been shown to best represent the actual shape of the demand curve over time, the curve used to describe the growth and decline of biological populations (Norton *et al*., 1976; McCulloch, 1994b, 1995b and 1999). There is however no fixed time cycle and some products reach maturity far sooner than others. In the short term (say ten to fifteen years) it may be permissible to forecast future demand on the basis of a relatively simple function based on the historical demand. A product in its early life could be forecast to grow at a rate governed by the growth in GDP (the compound growth model); similarly, one that has reached more mature status may have a linear growth rate, increasing by the same mass rate each year. The completely mature product will have reached a constant demand (and may, in fact, be subject to falling demand if there is replacement technology).

3.7.3 Modelling future sales and emissions from bottom-up methodologies

The first step is to construct a history of the demand for the material in its individual end-uses, both those where it is currently used and those where it has the potential to be used. These demands may then be extrapolated from starting points that reflect the current status. Although it is possible, given sufficient resources and access to much information that may be considered confidential, to construct separate demand models for each new compound (Enviros March, 1999; Haydock *et al*., 2003), the most common methodology involves constructing models of the overall demand in a particular sector, for example hermetic refrigeration. Extrapolation of that demand into the future can be based on a mathematical analysis of the prior changes in functions with time (as outlined above in McCulloch, 1994b, 1995b and 1999) or on the application of an external economic function, such as a compound growth rate (for example the growth in GDP as detailed in McFarland, 1999). Although over the relatively short time-period considered in this report (up to the year 2015), the difference between linear and compound growth for future demand may be small, any robust model should show the sensitivity of the forecasts to assumptions about future growth rates and should justify those rates by reference to the historic growth or models of comparable systems.

Once a forecast for the overall demand for a function has been established, the extent to which the HFC or PFC is deployed in that function can be estimated using a substitution fraction and a view of how that fraction might change in the future. There is now a body of data that describes recent substitution fractions and the changes expected in the coming decades (Enviros March, 1999; Forte, 1999; McFarland, 1999; Harnisch and Hendriks, 2000; Harnisch and Gluckman, 2001; Haydock *et al*., 2003). The most accurate substitution data will be found by examining current technical data for each compound in each application. In almost all cases, the potential for substitution is greater than the actual extent of substitution. Enforced changes in technology have provided the opportunity to switch to completely different materials and techniques (the not-in-kind solutions), to improve recovery and recycling (McFarland, 1999) and to significantly reduce charge in each installation (Baker, 1999). The requirements for continuing economic and environmental improvements will serve to drive these in the direction of further reductions in the substitution fractions.

Emission functions, factors applied to the quantities of material in use at each stage of the equipment life cycle, can also be predicted. In many studies the functions are based on AFEAS methodology, or variants of it. This allows for an initial loss, a loss during use and a final loss on disposal (AFEAS, 2003; McCulloch *et al*., 2001, 2003; Haydock *et al*., 2003; Enviros March, 1999; Harnisch and Hendriks, 2000). Default values for the emission functions for each category of end-use are provided in the IPCC Guidance on Good Practice in Emissions Inventories (IPCC, 2000a). However these emission functions have been shown to change in response to changes in technology and regulations (McCulloch *et al*., 2001) and predictions should take this into account, either explicitly or as a sensitivity case.

Finally the future evolution of emissions for each compound may be calculated by combining the temporally developed emission functions with the forecast demands. This approach of building a quantified description of emissions from databases that can be separately verified, requires a large body of information to be gathered. However, this can be reduced by making assumptions and by estimating quantities and parameters by analogy. During the course of this process it will be relatively easy to identify the parts of the analysis that rely on such assumptions and to calculate the sensitivities of the results to changes in them. This is much more difficult if 'top-down' methods are used because the assumptions are unlikely to be explicit.

3.7.4 *Modelling future sales and emissions using top-down parameterization*

This form of methodology uses forecast changes in major econometric parameters, such as GDP, to predict future emissions. A typical example is the series of scenarios for future emissions of HFCs and PFCs contained in the IPCC Special Report on Emissions Scenarios (IPCC, 2000b). Such long-term forecasts of emissions are desirable for predicting future climate change but the real implications of these forecasts need to be established and the predictions then need to be modified accordingly.

One significant advantage of top-down forecasting is that it depends on a parameter that should be common to all other forecasts of greenhouse-gas emissions – GDP or similar. It is therefore readily scaleableas expectations for the economic parameter change. However, the assumptions must be completely clear and the sensitivity of the result to changes in the assumptions must be an integral part of the analysis.

In the ideal case, the historical connection should be established between economic parameters and the demand for refrigeration, insulation and other categories in which HFCs and PFCs can be used, so that the parameter with the best fit can be chosen. Preferably, the analysis should be done on a regional or even a national basis, but it is unlikely that sufficient data would be available for this. Then the same methodology as used in the bottom-up models should be applied to translate this demand into emissions of individual compounds. In the form of this model it is unlikely that the timing of emissions can be rigorously estimated and so the sensitivity of the result to changes in the assumptions about the timing of emissions is essential. This allows the major failing of top-down models (that deviations from reality are perpetuated throughout the modelled period) to be addressed, with the possibility of making changes in the light of technological developments.

Technology change, diffusion and transfer

In all forms of modelling it is essential to establish the drivers of technological change and to assess their effects on demand. In the case of refrigeration and air conditioning as a whole, continuing improvements to system engineering have resulted in significant reductions in the absolute rates of leakage. In turn, this has allowed similar reductions in charge size, so that the inventory of refrigerants has been reduced together with the quantities required by original equipment manufacturers (OEMs) and for servicing. The scope for such reductions was reported in IPCC/TEAP (1999). Changes of this nature may originate in developed economies but is by no means confined to them. Furthermore, the adoption of new technology in the rest of the world could be expected to accelerate as the manufacturing base shifts from North America, Europe and Japan towards developing economies.

Predictions of future emissions need to take into account the probability of technical change, in terms of both the primary innovation and its diffusion and transfer into the global manufacturing sector. At the very least analyses of the sensitivities to such changes should be incorporated, which address both the magnitude and rate of change, and take into account both geographical and economic factors. Ideally a system should be developed to simply calculate their effects on the predictions.

Uncertainty
As the results are predictions, formal statistical analyses have relatively little meaning. The key to the exercise is how well these predictions will match the future reality and this cannot be tested now. However, the models can be subjected to certain tests and the simplest is replicating the current situation; models that cannot match this from historic data are likely to give meaningless predictions. If the model output does match with reality, then the sensitivity of the result to changes in the historic parameters will provide useful information for predictions of the future. Sensitivity analyses are likely to be the most that will be necessary. Given sufficient resources it may be possible to apply Monte Carlo methods to the predictions in order to derive a more statistically rigorous uncertainty for the result. However, the value of going to such lengths is questionable bearing in mind that the models are based on assumptions and not observations.

3.8 Outlook: Future methodological developments

Some of the assessment methodologies described in this chapter are very comprehensive. For example Life Cycle Assessment was developed for high volume products in mass markets and not for the customized systems found, for example, in commercial refrigeration or fire-protection. for certain areas of application or regions, the amount of resources required for some of these assessment methods will probably be considered inappropriate. There is an evident need for simple and pragmatic assessment methods in many world regions. TEWI and LCCP analyses – using standard assumptions and boundaries – are likely to have a strong role in fulfilling this need.

An important future task in using assessment methods such as TEWI and LCCP lies in achieving consistency and comparability among different studies from different authors and years. One example for this is the choice of weighting factors for the climate impact of emissions of different substances, for example, the choice of sets of GWP values which can come from the second or third IPCC assessment report or from other more recent sources, or the application of other metrics for the radiative impact of substance emissions (see Fuglestvedt *et al.* (2003) for an overview). It would therefore seem advisable for authors to publish enough interim results to allow the recalculation of modified parameters, such as more recent emission factors or values for indirect emissions from a country's electricity production.

In the past little attention was paid to ensuring the comparability and transferability of results from different technology assessments. The treatment of uncertainties was often incomplete and the resulting recommendations were often not robust enough to be transferred across a sector. Researchers and the users of their results should therefore pay more attention to determining the circumstances under which clear and robust conclusions on the relative performance of different technologies can be drawn, and on where uncertainties preclude such rankings. Carefully designed and performed sensitivity tests of the results for variations of key parameters are crucial for obtaining these insights.

In view of the many assumptions and different methodologies, an important role has been identified for comparisons between technologies using a common set of methods and assumptions as well as for the development of simple and pragmatic standard methodologies and the respective quality criteria. A future international standardization of simple as well as more complex or comprehensive evaluation methodologies will be important. An advanced level of international consistency has already been achieved in the field of health and safety. However, international standardization processes consume considerable amounts of time and resources (from scoping, via drafting and review to finalization). More timely and flexible processes will therefore be required as well. Whereas current standards are mainly based on low-toxicity, non-flammable fluids, standardization committees must also prepare proper standards which consider the limits and conditions for the safe use of fluids that are flammable or show higher toxicity. An essential input for this is the global standardization of international levels of requirements in respect to health, safety and environmental performance as well as respective test methods and classifications.

Policymakers need to have such information that is valid for entire sectors and this warrants additional methodology development. Future work will need to bridge the gap between application-specific comparisons and results which are robust enough to be used for policy design in entire subsectors. These analyses will have to be based on extensive databases on equipment populations, which comprise empirical data on fluid emissions and energy consumption. These databases should ideally be consistent and compatible with national greenhouse-gas emission inventories. Information on fluid sales to the different parties involved in the subsector will need to be made available. Significant resources will be required for these fairly comprehensive data requirements to support robust sectoral policies, and a number of resulting confidentiality issues will need to be addressed cautiously. In their efforts to achieve acceptability across subsectors, decision-makers could focus on increasing the involvement of relevant stakeholders and introducing additional measures to increase the transparency for outside users by means of more extensive documentation.

It is important to bear in mind that the methodologies and policies discussed above may be subject to misuse and neglect. For example, although industry uses such assessments, they are rarely determining factors in selecting a particular alternative. In fact, environmental assessment methods that are sensitive to inputs are often employed to justify the suitability of a technology that has already been selected for other reasons.

Policymakers should therefore recognize other parameters industry uses to choose technologies, so that they are aware of the factors affecting the outcomes of an analysis and of the market forces which may counter the spirit of environmental policies.

Cost is clearly one of the most important factors driving decisions for or against certain technologies. Private decision-makers usually take a life-cycle cost perspective based on their enterprises' rules for depreciation times and capital costs for their investment. Policymakers commonly use different rules and parameters to judge the cost-effectiveness of different measures. As this Special Report has shown, there is still little public cost information available which policymakers can use to reach a judgement about the cost-effectiveness of measures. Many firms give considerably less weight to social costs than to private costs in making their decisions. Initial exploratory studies would seem to be a worthwhile means of filling this gap. In the future it might be useful to apply uniform costing methodologies with common standards for transparency and data quality.

In summary the following points can be highlighted as key results:

A systems perspective is usually used to select a technology. This takes into account the system's life-cycle costs, its energy consumption and associated emissions, health and safety impacts, and other environmental impacts. The available assessment methods for each of these attributes have been described in this chapter. These will often need to be adapted to the specific application region concerned. A decision-maker can avoid inconsistencies by initiating concerted technology comparisons of competing technologies under common rules. In any case decision-makers need to make their decisions in the light of the remaining uncertainties and limitations of the available assessment methods, such as Total Equivalent Warming Impact (TEWI), the Life Cycle Climate Performance (LCCP) or a Life Cycle Assessment (LCA).

Ensuring the faithful application of existing assessment methodologies by all players in order to provide information relevant for decisions, is an ongoing challenge. A decision-maker may want to ensure that the full life cycle of the application has been considered, that all relevant stakeholders have been involved in the scoping and execution of the analysis and in the review of its results, that accepted emissions monitoring protocols have been applied for direct and indirect emissions, that all costs are properly accounted based in the best available figures, and that the uncertainties, sensitivities and limitations of the analysis have all been clearly identified.

EXECUTIVE SUMMARY

Domestic refrigeration

Domestic refrigerators and freezers are used throughout the world for food storage in dwelling units and in non-commercial areas such as offices. More than 80,000,000 units are produced annually with internal storage capacities ranging from 20 litre to greater than 850 litre. With an estimated average unit lifespan of 20 years, this means there is an installed inventory of approximately 1500 million units. As a result of the Montreal Protocol, manufacturers initiated transition from CFC refrigerant applications during the early 1990s. This transition has been completed in developed countries and significant progress has been made in developing countries. The typical lifespan for domestic refrigerators means that products manufactured using CFC-12 refrigerant still comprise approximately one-half of units in the installed base. This has significantly slowed down the rate of reduction in the demand for CFC-12 refrigerant in the servicing sector.

Isobutane (HC-600a) and HFC-134a are the dominant alternative refrigerants for replacing CFC-12 in new domestic refrigeration appliances. Each of these has demonstrated mass production capability for safe, efficient, reliable and economic use. Both refrigerants give rise to similar product efficiencies. Independent studies have concluded that application design parameters introduce more efficiency variation than that attributable to the refrigerant choice. Comprehensive refrigerant selection criteria include safety, environmental, functional, cost and performance requirements. The choice of refrigerant can be strongly influenced by local regulatory and litigation environments. Each refrigerator typically contains 50–250 grams of refrigerant contained in a factory-sealed hermetic system. A simplified summary of the relative technical considerations for these two refrigerants is:

- HC-600a uses historically familiar mineral oil lubricants. Manufacturing processes and designs must fully take into account the flammable nature of the refrigerant. For example, the need for proper factory ventilation and appropriate electrical equipment, preventing leaking refrigerant from gaining access to electrical components, using sealed or non-sparking electrical components, and the use of proper brazing techniques or preferably the avoidance of brazing operations on charged systems. Service procedures must similarly include appropriate precautions for working with flammable refrigerants;
- HFC-134a uses moisture-sensitive polyolester oils. Manufacturing processes should ensure that low moisture levels are maintained. Long-term reliability requires a more stringent avoidance of contaminants during production or servicing compared to either CFC-12 or HC-600a practices.

The use of the hydrocarbon blend propane (HC-290)/isobutane (HC-600a) allows CFC-12 volumetric capacity to be matched and avoids the capital expense of retooling compressors. These blends introduce manufacturing complexities and require the use of charging techniques suitable for refrigerant blends which have components with different boiling points. The application of these blends in Europe during the 1990s was an interim step towards the transition to HC-600a using retooled compressors. The same safety considerations apply to hydrocarbon blends as to HC-600a.

Alternative refrigeration technologies such as the Stirling cycle, absorption cycle, thermoelectrics, thermionics and thermoacoustics continue to be pursued for special applications or for situations with primary drivers that differ from conventional domestic refrigerators. These technology options are not expected to significantly alter the position of vapour compression technology as the choice for domestic refrigeration.

Vapour compression technology is mature and readily available worldwide. The availability of capital resources is dictating the timing of conversion to HC-600a and HFC-134a. Current technology designs typically use less than half the electrical energy required by the units they replace. This reliable performance is provided without resorting to higher cost or more complex designs. Continued incremental improvements in unit performance and/or energy efficiency are anticipated. Government regulations and voluntary agreements on energy efficiency and labelling programmes have demonstrated their effectiveness in driving improved efficiency product offerings in several countries.

Good design and the implementation of good manufacturing and service practices will minimize refrigerant emissions; however, special attention must be given to the retirement of the large number of units containing CFC-12. With a typical 20-year lifespan, refrigerator end-of-life retirement and disposal happens to about 5% of the installed base each year. This means approximately 75 million refrigerators containing 100 grams per unit, or 7500 total tonnes of refrigerant are disposed of annually. This refrigerant will be predominantly CFC-12 for at least another 10 years. The small refrigerant charge means that refrigerant recovery is not economically justifiable. Regulatory agencies around the world have therefore provided incentives or non-compliance penalties to promote recovery of this ODS.

In 2002, the total amount of refrigerants banked in domestic refrigeration amounted to 160,000 tonnes, with annual refrigerant emissions of 5.3% of banked system charge. The annualized HFC emissions rate from this sector was 1.0% in 2002. HFC emissions mostly occur during useful life. Production transition to HFCs started during 1995; consequently in 2002 the installed product age was 7 years or less compared to a typical lifespan of 20 years. Further, recovery during service and disposal is required in most early conversion countries.

Commercial refrigeration

Commercial refrigeration makes fresh and frozen food available to customers at the appropriate temperature levels: chilled food in the range of 1°C–14 °C and frozen food in the range of –12°C to –20°C.

On a global basis, commercial refrigeration is the refrigeration subsector with the largest refrigerant emissions calculated as CO_2-equivalents. This amounts to 40% of the total annual refrigerant emissions, see Table 11.5. In 2002 worldwide commercial refrigeration emission rates were reported to be 30% yr^{-1} of the installed commercial refrigeration banked inventory of 605,000 tonnes refrigerant. This means that in an environment with an average energy mix, the refrigerant emissions represent about 60% of the total emissions of GHG resulting from system operation, the rest being indirect emissions caused by power production.

Refrigeration equipment types vary considerably in terms of size and application. Stand-alone equipment consists of systems where the components are integrated, such as beverage vending machines, ice cream freezers and stand-alone display cases. Refrigerant charge sizes are small (0.2–1 kg), and the CFCs CFC-12 and R-502 are being replaced by HFCs HFC-134a, R-404A and R-507A. HCFC-22 is also used, but is subject to phase-out requirements. Refrigerant emissions are low in these mainly hermetic systems and are similar to domestic refrigerator emissions. However, end-of-life recovery is almost non-existent on a global basis and this results in an average annual leakage of 7–12% of the refrigerant charge, dependent on the equipment lifetime. Some stand-alone equipment using hydrocarbons as refrigerants have been developed and are available in European countries, with refrigerant charge sizes in accordance with the limitations imposed by European and national safety standards.

Condensing units are small commercial systems with compressors and condensers located external to the sales area, and the evaporators located in display cases in the sales area, or in a cold room for food storage. These units are installed in shops such as bakeries, butchers and convenience stores as well as in larger food retailer stores. Similar refrigerants are used in these applications as in stand-alone equipment; however, with the larger refrigerant charges in these systems (1–5 kg), hydrocarbon refrigerant applications may be limited by national safety standards. Refrigerant emissions depend on the robustness of the system design, installation, monitoring and refrigerant recovery at end of equipment lifetime.

Full supermarket systems can be categorized by whether refrigerant evaporation occurs in the display cabinets and cold stores, or whether a low-temperature, secondary heat transfer fluid that is cooled centrally, is circulated to the display cabinets and cold stores. The first type is termed a direct system and the second type an indirect system.

Supermarket centralized direct systems consist of a series of compressors and condensers located in a remote machinery room, providing a cooling medium to display cabinets and cold storage rooms in other parts of the building. The size of systems can vary from cooling capacities of 20 kW to more than 1 MW, as used in larger supermarkets. Refrigerant charge sizes can range from 100–2000 kg. The most common form of centralized system is direct expansion. Specific units can be dedicated to low-temperature or medium-temperature evaporators. HCFC-22 continues to be extensively used in these systems, with R-502 for low-temperature applications being replaced by R-404A and R-507A. Due to European regulations on HCFCs that have been in force since January 2001, R-404A and R-507A are the most commonly used refrigerants for large capacity low- and medium-temperature systems in Europe.

The 'distributed' system is a variation of the direct system. In this the compressors are located in sound-proof boxes near the display cases, permitting the shortening of refrigerant circuit length and a corresponding 75% reduction of refrigerant charge. Condensing units can be air-cooled or water-cooled. When compressor systems are installed as small packs with roof-mounted, air-cooled condensers, or as small packs adjacent to the sales area in conjunction with remote air-cooled condensers, they are sometimes referred to as close coupled systems. The refrigerants used are mainly HCFC-22 and the low-temperature refrigerants R-404A and R-507A. Other refrigerants such as R-410A are also being considered. With the close-coupled system design, refrigerant emissions are estimated to be 5–7% of charge on an annual basis. Compared to the centralized systems, the absolute reduction in refrigerant emissions is much greater due to the considerable reduction in refrigerant charge size.

The design of indirect systems for supermarkets permits refrigerant charge size reduction of 75–85%. Fluorocarbon-based refrigerants are generally used in these systems. However, if the centralized refrigeration system can be located in a controlled-access room away from the customer area, indirect systems may also use flammable and/or toxic refrigerants, dependent on system safety measures and national safety regulations. Refrigerant emissions are reduced to about 5% of charge yr^{-1} due to the reductions in the reduced piping lengths and the number of connecting joints.

Systems that use ammonia and hydrocarbons as primary refrigerants in indirect systems operate in several European countries. Published results show that ammonia and hydrocarbon indirect systems have a 10–30% higher initial cost than direct expansion systems and an energy consumption 0–20% higher than that of direct expansion systems, due to the additional system requirements (heat exchanger and circulating pumps with their costs and energy penalties). Development work on indirect systems design is continuing with the goals of reducing the cost and energy penalties in these systems.

Carbon dioxide is being evaluated in direct systems for both low- and medium-temperature applications, and in cascade systems with carbon dioxide at the low-temperature stage and ammonia or R-404A at the medium-temperature stage. Thirty cascade systems have been installed in supermarkets and the initial costs and energy consumption are reported to be similar to R-404A direct expansion systems.

Important considerations in the selection of designs for supermarket refrigeration systems and refrigerants are safety, initial cost, operating cost and climate change impact (refrigerant emissions and carbon dioxide from electricity produced to operate the refrigeration systems). In the 1980s the centralized direct systems had annual refrigerant emissions up to 35% of charge. Recent annualized emission rates of 3–22% (average

18%) were reported for 1700 supermarket systems in several European countries and the USA. The reduced emission rates were due to a combination of factors aimed at improving refrigerant containment, such as system design for tightness, maintenance procedures for early detection and repairs of leakage, personnel training, system leakage record keeping, end-of-life recovery of refrigerant and in some countries, increasing the use of indirect cooling systems.

In 2002, worldwide commercial refrigeration emission rates were reported to be 30% yr^{-1} of the installed commercial refrigeration banked inventory of 605,000 tonnes of refrigerant. The higher worldwide emission rates indicate less attention was paid to refrigerant containment and end-of-life recovery than in the limited survey data reported above.

Traditional supermarket centralized direct systems must be designed for lower refrigerant emissions and higher energy efficiency in order to reduce climate change impact. From an overall perspective, significant research and development is underway on several designs of supermarket refrigeration systems to reduce refrigerant emissions, use lower global-warming refrigerants and reduce energy consumption. Life cycle climate performance calculations indicate that direct systems using alternative refrigerants, distributed systems, indirect systems and cascade systems employing carbon dioxide will have significantly lower CO_2-equivalent emissions than centralized direct systems that have the above-stated, historically-high refrigerant emission rates.

Food processing, cold storage and industrial refrigeration

Food processing and cold storage is one of the important applications of refrigeration for preserving and distributing food whilst keeping food nutrients intact. This application of refrigeration is very significant in terms of size and economic importance in both developed and developing countries. The annual consumption of frozen food worldwide is about 30 Mtonnes yr^{-1}. Over the past decade, consumption has increased by 50% and is still growing. The amount of chilled food is about 10–12 times greater than the supply of frozen products. Frozen food in long-term storage is generally kept at –15°C to –30°C, while –30°C to –35°C is typical for freezing. Chilled products are cooled and stored at temperatures from –1°C–10°C.

The majority of refrigeration systems for food processing and cold storage are based on reciprocating and screw compressors. Ammonia, HCFC-22, R-502 and CFC-12 are the refrigerants historically used, with other refrigerant options being HFCs, CO_2 and hydrocarbons. HFC refrigerants are being used instead of CFC-12, R-502 and HCFC-22 in certain regions. The preferred HFCs for food processing and cold storage applications are HFC-134a and HFC blends with an insignificant temperature glide such as R-404A, R-507A and R-410A. Ammonia/CO_2 cascade systems are being introduced in food processing and cold storage.

Some not-in-kind (non-vapour compression) technologies, such as vapour absorption technology and compression-absorption technology, can be used for food processing and cold storage applications. Vapour absorption technology is well established, whereas compression-absorption technology is still under development.

For this category, limited data are available on TEWI/LCCP. A recent study of system performance and LCCP calculations for a 11 kW refrigeration system operating with R-404A, R-410A and HC-290 showed negligible differences in LCCP, based on the assumptions used in the calculations.

Industrial refrigeration includes a wide range of cooling and freezing applications in the chemical, oil and gas industries as well as in industrial ice-making, air liquefaction and other related industry applications. Most systems are vapour compression cycles, with evaporator temperatures ranging from 15°C down to –70°C. Cryogenic applications operate at even lower temperatures. Capacities of units vary from 25 kW to 30 MW, with systems often being custom made and erected on-site. Refrigerant charge size varies from 20–60,000 kg. The refrigerants used are preferably single component or azeotropes, as many of the systems use flooded evaporators to achieve high efficiency. Some designs use indirect systems (with heat transfer fluids) to reduce refrigerant charge size and to the risk of direct contact with the refrigerant.

These refrigeration systems are normally located in industrial areas with limited public access, and ammonia is the main refrigerant. The second refrigerant in terms of volume use is HCFC-22, although the use of HCFC-22 in new systems is forbidden for all types of refrigerating equipment by European regulations since January 2001. Smaller volume CFC refrigerants CFC-12 and R-502 are being replaced by HFC-134a and R-404A, and R-507A and R-410A. CFC-13 and R-503 are being replaced by HFC-23 and R-508A or R-508B. HCFC-22 is being replaced by R-410A, as the energy efficiency of R-410A is slightly higher than that of HCFC-22. The energy efficiency of R-410A can be similar to that of ammonia for evaporation temperatures down to –40°C, dependent on the compressor efficiency. Hydrocarbon refrigerants have historically been used in large refrigeration plants within the oil and gas industry.

Carbon dioxide is another non-HFC refrigerant which is starting to be used in industrial applications, as the energy efficiency of carbon dioxide systems can be similar to that of HCFC-22, ammonia and R-410A in the evaporator temperature range of –40°C to –50°C for condensing temperatures below the 31°C critical temperature of carbon dioxide. Cascade systems with ammonia in the high stage and carbon dioxide in the low stage show favourable cost and energy efficiency. Carbon dioxide is also being used as a heat-transfer fluid in indirect systems.

Attempts are being made to reduce refrigerant emissions in industrial refrigeration, food processing and cold storage by improving the system design, minimizing charge quantities, ensuring proper installation, improving the training of service personnel with respect to the detection of potential refrigerant leakage, and improving procedures for recovery and re-use of refrigerant. The total amount of refrigerants banked in the combined sectors of industrial refrigeration, food processing and cold storage was 298,000 tonnes in 2002, with ammonia at 35% and HCFC-22 at 43% of the total banked inventory. Annual refrigerant emissions were 17% of banked system charge.

Transport refrigeration

Transport refrigeration consists of refrigeration systems for transporting chilled or frozen goods. Transport takes place by road, rail, air and sea; further, containers as refrigerated systems are used with moving carriers. All transport refrigeration systems must be sturdily built to withstand movements, vibrations and accelerations during transportation, and be able to operate in a wide range of ambient temperatures and weather conditions. Despite these efforts, refrigerant leakage continues to be a common issue. It is imperative that refrigerant and spare system parts are available on-board and along the transport routes. Ensuring safe operation with all working fluids is essential, particularly in the case of ships where there are limited options for evacuation.

Ships with cargo-related, on-board refrigeration systems have either refrigerated storage spaces or provide chilled air supply. There are about 1100 such ships, with HCFC-22 being the main refrigerant. In addition, there are approximately 30,000 merchant ships which have refrigerated systems for crew food supply, again mainly using HCFC-22. Alternative refrigerants being implemented are R-404A/R-507A, R-410A, ammonia and ammonia/CO_2.

Refrigerated containers allow storage during transport on rail, road and seaways. There are more than 500,000 such containers that have individual refrigeration units of about 5 kW cooling capacity. Refrigerants in this sector are transitioning from CFC-12 to HFC-134a and R-404A/R-507A.

Refrigerated railway transport is used in North America, Europe, Asia and Australia. The transport is carried out with either refrigerated railcars, or, alternatively, refrigerated containers (combined sea-land transport; see Section 4.6.2) or swap bodies (combined road-land transport; see Section 4.6.4).

Road transport refrigeration systems (with the exception of containers) are truck-mounted systems. The refrigerants historically used were CFC-12, R-502 and HCFC-22. New systems are using HFC-134a, R-407C, R-404A, R-410A and decreasing amounts of HCFC-22. There are about 1 million vehicles in operation, and annual refrigerant use for service is reported to be 20–25% of the refrigerant charge. These high leakage rates call for additional design changes to reduce leakage, which could possibly follow the lead of newer mobile air-conditioning systems. Another option would be for systems to use refrigerants with a lower global-warming potential (GWP).

The non-HFC refrigerant hydrocarbons, ammonia and carbon dioxide are under evaluation, and in some cases these are being used for transport applications in the various sectors, with due consideration for regulatory, safety and cost issues. Fishing trawlers in the North Pacific Ocean already use ammonia for refrigeration, with a smaller number of trawlers using R-404A or R-507A. Carbon dioxide is a candidate refrigerant for low-temperature refrigeration, but the specific application conditions must be carefully considered. Carbon dioxide systems tend towards increased energy consumption during high-temperature ambient conditions, which may be significant when containers are closely stacked on-board ships, leading to high condensation/gas cooler temperatures because of lack of ventilation. In the case of reefer ships and fishing vessels, a promising alternative technology is equipment with ammonia/carbon dioxide systems. These systems have similar energy efficiency to existing refrigeration systems but higher initial costs.

Low GWP refrigerant options will technically be available for transport refrigeration uses where fluorocarbon refrigerants are presently used. In several cases, these low GWP options may increase the costs of the refrigeration system, which is an important consideration for owners of transport equipment. A technology change from an HFC, such as R-404A, to a low-GWP fluid will usually lead to a reduction of TEWI, if the energy consumption is not substantially higher than in existing systems.

The total amount of refrigerants banked in transport refrigeration was 16,000 tonnes in 2002, with annual refrigerant emissions of 38% of banked system charge consisting of CFCs, HCFCs and HFCs.

4.1 Introduction

The availability and application of refrigeration technology is critical to a society's standard of living. Preservation throughout the food chain and medical applications are examples of key contributors to quality of life. Integrated energy consumption information is not available, but this largest demand sector for refrigerants is estimated to use about 9% of world power generation capacity (Bertoldi, 2003; EC, 2003; ECCJ, 2004; EIA, 2004; ERI, 2003; UN-ESCAP, 2002, Table 1.1.9). This consumption of global power-generation capacity means that the relative energy efficiency of alternatives can have a significant impact on indirect greenhouse-gas (GHG) emissions.

Refrigeration applications vary widely in size and temperature level. Sizes range from domestic refrigerators requiring 60–140 W of electrical power and containing 40–180 g of refrigerant, to industrial and cold storage refrigeration systems with power requirements up to several megawatts and containing thousands of kilograms of refrigerant. Refrigeration temperature levels range from –70°C to 15°C. Nearly all current applications use compression-compression refrigeration technology. The potential market size for this equipment may approach US$ 100,000 million annually. This diversity has resulted in unique optimization efforts over the decades, which has resulted in solutions optimized for different applications. For discussion purposes, the refrigeration sector is divided into the five subsectors:

- Domestic Refrigeration: the refrigerators and freezers used for food storage primarily in dwelling units;
- Commercial Refrigeration: the equipment used by retail outlets for holding and displaying frozen and fresh food for customer purchase;
- Food Processing and Cold Storage: the equipment to preserve, process and store food from its source to the wholesale distribution point;
- Industrial Refrigeration: the large equipment, typically 25 kW to 30 MW, used for chemical processing, cold storage, food processing and district heating and cooling;
- Transport Refrigeration: the equipment to preserve and store goods, primarily foodstuffs, during transport by road, rail, air and sea.

Data in Table 4.1 indicate that the annualized refrigerant emission rate from the refrigeration sector was 23% in 2002. This includes end-of-life losses. There is a wide range of annualized emissions from the five subsectors, from 5% for domestic refrigeration to 30% for commercial refrigeration to 38% for transport refrigeration. For commercial refrigeration, the 30% annual refrigerant emissions represent typically 60% of the total emissions of GHGs resulting from system operation, the rest being indirect emissions from power production. This indicates the importance of reducing refrigerant emissions from this sector, in addition to the importance of the energy efficiency of systems stated above.

4.2 Domestic refrigeration

4.2.1 Background

Domestic refrigerators and freezers are used for food storage in dwelling units and in non-commercial areas such as offices throughout the world. More than 80,000,000 units are produced annually with internal storage capacities ranging from 20 litre to greater than 850 litre. With an estimated typical unit life of 20 years (Weston, 1997), the installed inventory is approximately 1500 million units. Life style and food supply infrastructures strongly influence consumer selection criteria, resulting in widely differing product configurations between different global regions. Products are unitary factory assemblies employing hermetically-sealed, compression refrigeration systems. These typically contain 50–250 g of refrigerant.

4.2.2 Refrigerant options

Conversion of the historic application of CFC-12 refrigerant in these units to ozone-safe alternatives was initiated in response to the Montreal Protocol. Comprehensive refrigerant selection criteria include safety, environmental, functional, performance and cost requirements. A draft refrigerant selection-decision map and a detailed discussion of requirements were included in the 1998 report of the Refrigeration, Air Conditioning, and Heat Pumps Technical Options Committee (UNEP, 1998). The integration of these requirements with other potential drivers such as global-warming emissions reduction, capital resource availability and energy conservation results in a comprehensive analysis of refrigerant options for strategic consideration. Two different application areas must be addressed: (1) new equipment manufacture, and (2) service of the installed base. New equipment manufacture can be addressed more effectively, since the ability to redesign avoids constraints and allows optimization.

4.2.2.1 New Equipment Refrigerant options

Most new refrigerators or freezers employ either HC-600a or HFC-134a refrigerant. Each of these refrigerants has demonstrated mass production capability for safe, efficient, reliable and economic use. There are no known systemic problems with properly manufactured refrigerator-freezers applying either of these primary options. The key variables influencing selection between these two refrigerants are refrigerator construction details, energy efficiency, building codes, environmental considerations and the economics of complying with standards. Other selected alternative refrigerants or selected refrigerant blends have had limited regional appeal, driven by either niche application requirements or by availability of suitable compressors or refrigerants. Some brief comments about selected refrigerant use are now given.

Isobutane (HC-600a) refrigerant

HC-600a applications use naphthenic mineral oil, the historic

choice for CFC-12 refrigerant, as the lubricant in the hermetic system. Competent manufacturing processes are required for reliable application but cleanliness control beyond historic CFC-12 practices is not required. HC-600a has a 1.8% lower flammability limit in air, increasing the need for proper factory ventilation and appropriate electrical equipment. This flammable behaviour also introduces incremental product design and servicing considerations. These include preventing leaking refrigerant access to electrical components or using sealed or non-sparking electrical components, using proper brazing methods or preferably avoiding brazing operations on charged systems, and ensuring a more robust protection of refrigerant system components from mechanical damage to help avoid leaks.

HFC-134a refrigerant: HFC-134a applications require synthetic polyolester oil as the lubricant in the hermetic system. This oil is moisture sensitive and requires enhanced manufacturing process control to ensure low system moisture level. HFC-134a is chemically incompatible with some of the electrical insulation grades historically used with CFC-12. Conversion to the electrical insulation materials typically used for HCFC-22 applications may be necessary. HFC-134a is not miscible with silicone oils, phthalate oils, paraffin oils or waxes. Their use should be avoided in fabrication processes for components in contact with the refrigerant. Common items for concern are motor winding lubricants, cutting fluids in machining operations and drawing lubricants. Careful attention to system cleanliness is required to avoid incompatible contaminants. Trace contaminants can promote long-term chemical degradation within the system, which can reduce cooling capacity or cause system breakdown. Necessary process controls are not technically complex but do require competent manufacturing practices and attention to detail (Swatkowski, 1996).

Isobutane (HC-600a)/propane (HC-290) refrigerant blends
The use of these hydrocarbon blends allows matching CFC-12 volumetric capacity and avoids capital expense for retooling compressors. These blends introduce design and manufacturing complexities. For example, they require charging techniques suitable for use with blends having multiple boiling points. The use of HC-600a/HC-290 blends in Europe during the 1990s was an interim step towards a final transition to HC-600a using retooled compressors. Unique application considerations are consistent with those discussed above for HC-600a**.**

Other refrigerants and refrigerant blends
Example applications of additional refrigerants in new equipment include HC-600a/HFC-152a blends in Russia, HCFC-22/HFC-152a blends in China and HCFC-22 replacing R-502 in Japan. These all are low volume applications supplementing high-volume primary conversions to HC-600a or HFC-134a refrigerant. Demand for <u>all</u> refrigerants other than HC-600a and HFC-134a totals less than 2% of all Original Equipment Manufacturer (OEM) refrigerant demand (UNEP, 2003). These special circumstance applications will not be further discussed in this report.

4.2.2.2 Service of existing equipment
Service options range from *service* with original refrigerant, to *drop-in*, where only the refrigerant is changed, to *retrofit*, which changes the refrigerant and other product components to accommodate the specific refrigerant being used. Several binary and ternary blends of various HFC, HCFC, PFC and hydrocarbon refrigerants have been developed to address continuing service demand for CFC-12. These blends are tailored to have physical and thermodynamic properties compatible with the requirements of the original CFC-12 refrigerant charge. Their application has been successful and is growing. Some of these are near-azeotrope blends; others have disparate boiling points or glide. If refrigerants and lubricants other than original design specification are proposed for use, their compatibility with the specific refrigerator-freezer product configuration and its component materials must be specifically reviewed. An extended discussion of domestic refrigerator service options was included in the 1998 Report of the Refrigeration, Air Conditioning and Heat Pumps Technical Options Committee (UNEP, 2003).

4.2.3 Not-in-kind alternatives

Alternative refrigeration technologies such as the Stirling cycle, absorption cycle, thermoelectrics, thermoacoustics and magnetic continue to be pursued for special applications or situations with primary drivers that differ from conventional domestic refrigeration. Two examples of unique drivers are portability or absence of dependence on electrical energy supply. The 1994 Report of the Refrigeration, Air Conditioning and Heat Pumps Technical Options Committee concluded that no identified technology for domestic refrigerator-freezers was competitive with conventional compression-compression technology in terms of cost or energy efficiency (UNEP, 1994). The 1998 and 2002 reports of this committee reaffirmed this conclusion (UNEP, 1998; UNEP, 2003). No significant near-term developments are expected to significantly alter this conclusion.

4.2.4 Energy efficiency and energy standards

Relative refrigerator energy efficiency is a critical parameter in the assessment of alternatives. In practice, similar refrigeration system efficiency results from the use of either HFC-134a or HC-600a refrigerant. Independent studies have concluded that the relative energy efficiencies of these two primary alternatives are comparable. Efficiency differences from normal manufacturing variation exceed the differences introduced by the refrigerant choice (Sand *et al*., 1997; Fischer *et al.,* 1994; D&T, 1996; Wenning, 1996). Energy efficiency of a product is strongly influenced by configuration, component hardware selection,"thermal insulation, heat exchange surfaces and control algorithms. Effective options are readily available from multiple commercial sources. The improved energy efficiency of domestic refrigeration products is a national initiative in several countries. Energy labelling and energy standards are both being effectively used to facilitate these initiatives. The

Collaborative Labelling and Appliance Standards Program (CLASP) maintains a website with substantive information including links to various national programmes (URL: http://www.clasponline.org).

Energy standards and tests procedures
Energy test procedures provide the basis for energy regulations and labelling initiatives. These test procedures must be reproducible and repeatable and should ideally provide an indication of energy consumption under consumer use conditions. They should also provide an effective amendment protocol to accommodate evolving product technologies. Test procedures have been developed by several global standards organizations. The tests are different, and the results from one should never be directly compared with the results from another. Each can provide a relative energy consumption value for the test conditions specified. The interested reader is referred to instructive discussions and comparisons of energy test procedures, their limitations and their future needs (Bansal and Kruger, 1995; Meier and Hill, 1997; Meier, 1998).

4.2.5 Consumption and consumption trends

Table 4.2 presents consumption of the three most used domestic refrigerator refrigerants during 1992, 1996 and 2000 (UNEP, 2003). Table 4.3 presents consumption details by global region for the year 2000 (UNEP, 2003). New equipment conversions from CFC-12 to ozone-safe alternatives are occurring in advance of the Montreal Protocol requirements. By the year 2000, 76% of new unit production had been converted: 53% to HFC-134a, 21% to HC-600a and 2% to all other (UNEP, 2003). Subsequent developments have maintained this trend with an apparent increase in the percentage converting to hydrocarbon refrigerants. Two large market examples are the production in India converting to either HFC-134a or an HC-600a/HC-290

blend (UNEP, 2000) and some units converting from HFC-134a to HC-600a in Japan.

Conversion of the service demand has been less successful. Field service procedures typically use the originally specified refrigerants. The long useful product life (up to 30+ years for some units with an average around 20 years), large installed base (approximately 1500 million units) and uncertainties with field conversion to alternative refrigerants have resulted in a strong continuing service demand for CFC-12. The estimated percentage of refrigerators requiring post-warranty service of the hermetically sealed system and replacement of the original refrigerant charge at sometime during their service life is 1% in industrialized countries and 7% in developing countries. In industrialized countries this demand is typically satisfied with reclaimed or stockpiled CFC-12 when not contrary to local regulations. (Note: 'Reclaimed' refrigerant refers to recovered refrigerant that has been purified to original specifications. Unpurified recovered refrigerant should never be used in long-life domestic refrigerators. Probable impurities are likely to catalyze systems degradation and cause premature failures.) CFC-12 is normally the lowest cost refrigerant in developing countries. Regardless of location, use of the CFC-free refrigerant service blends mentioned above only becomes significant when CFC-12 availability becomes limited. Since post-warranty service is typically provided by small, independent businesses, reliable service demand data are not available. Further, the limited capital resources in developing countries promotes the labour-intensive refurbishing of units compared to retirement and replacement with new units. This not only prolongs the phase-out of CFC-12, but also results in increased failure rates from the highly variable quality of workmanship.

4.2.6 *Factors affecting emissions*

A text-box example included in Chapter 3 of this report (see Table 3.5) tabulates emission factors which must be considered for comprehensive Life Cycle Climate Performance (LCCP) or Total Equivalent Warming Impact (TEWI) of domestic refrigeration design options. There are two general types of emissions: *direct*, which for discussion of the refrigerant choice are limited to the refrigerant itself; and *indirect*, which depends on the refrigerator design and the infrastructures of supporting services in the use environment (Sand *et al*., 1997). The emission of insulating foam blowing-agents is not addressed in this chapter. Insulating foam is addressed in Chapter 7

Direct emissions

Efficient factory operations and effective process and product designs will minimize emissions at the start of the product life cycle. Significant process variables include refrigerant transfer and storage, charge station operations, maintenance protocols and factory process efficiencies. Key refrigerator design variables include hermetic-system internal volume, number of joints, mechanical fatigue and abuse tolerance and, of course, the choice of refrigerant. Domestic refrigerators contain refrigerant in factory-sealed, hermetic systems. Once sealed, refrigerant emission can only occur if there is a product defect or quality issue. Typical examples are brazing defects or containment component fatigue. In all cases, excluding life-ending failures, the defect will require the product hermetic system to be repaired. Variables influencing emissions during service include refrigerant recovery procedure usage and efficiency, charge technique employed, technician training and technician work standards. Refrigerant recovery during service is practiced in many countries. The small refrigerant charge quantity, typically 50–250 g per unit, make this recovery economically unattractive. Regulations and non-compliance penalties are usually required to provide incentives for recovery. Audits and refrigerant charge logs can provide useful metrics for the quality of refrigerant recovery practices.

Clodic and Palandre (2004) have detailed worldwide refrigerant bank and emissions data for domestic refrigerators (see Table 4.1). CFC emissions for domestic refrigeration in 2002 were estimated to be 8000 tonnes. HFC emissions for domestic refrigeration in 2002 were estimated to be 0.3% of the domestic refrigerant bank, or 500 tonnes. Domestic HFC refrigerant emission estimates will have increased in 2015 to 3000–8000 tonnes, dependent on the extent of refrigerant containment and recovery assumed.

With a typical 20-year lifespan, refrigerator end-of-life retirement and disposal happens to about 5% of the installed base every year. In quantified terms this means approximately 75 million refrigerators containing approximately 100 g per unit or 7500 total tonnes of refrigerant are retired and disposed of annually. For the next few years, or possibly even decades, CFC-12-containing product will continue to be a significant fraction of the waste stream. As is the case for service recovery, the small refrigerant charge makes end-of-life recovery uneconomical. Equipment and procedures commonly used for refrigerant recovery during service can be used but recovery is more typically accomplished in central disposal locations. This allows the use of faster, less labour-intensive procedures to moderate recovery costs. Nevertheless, regulations and non-compliance penalties normally provide incentives for this recovery. Regulating agencies in various global regions administer these requirements and are an appropriate source for further information.

Indirect emissions

Product design affects indirect emissions through refrigerator operating efficiency, and ease of refrigerator disassembly and separation for recycling. Higher efficiency units consume less electricity which, in turn, proportionately reduces the emissions derived from electrical power generation and distribution. Parameters influencing energy efficiency are fundamental design considerations such as heat exchangers, control efficacy, refrigerant systems, heat losses, parasitic power demands such as fans and anti-sweat heaters and product safety. The design approaches taken and options selected are directly related to the desired product features, performance and regulatory environment. A comprehensive discussion of detailed design parameters is beyond the scope of this report. Information is commercially available from multiple sources. Example references listing areas of opportunity are the UNEP Refrigerants Technical Options Committee assessment reports (UNEP, 1994, 1998, 2003), the International Energy Agency energy efficiency policy profiles report (IEA, 2003) and the Arthur D. Little global comparative analysis of HFC and alternative technologies (ADL, 2002). Objective discussions of many options are contained in the Technical Support Documents of the US Department of Energy rulemakings for domestic refrigerators and freezers (US DOE, 1995).

4.2.7 *Comparison of emissions from alternative technologies*

HFC-134a and HC-600a are clearly the significant alternative refrigerants for domestic refrigeration. Consequently, the significant global-warming emissions comparison for this application sector is HFC-134a compared to HC-600a. An accurate comparison of these is very complex. The multiple and widely diverse product configurations available globally are the consequence of consumer needs and choices. Comparative analysis results will be influenced by the example scenario selected and its assumed details. The available degrees of freedom are too high to achieve a comprehensive perspective within a manageable number of scenarios. Any single technical solution will not provide an optimized solution.

Harnisch and Hendriks (2000) and March (March, 1998) estimated the conversion cost from HFC-134a to HC-600a, expressed as unit emissions avoidance cost. Harnisch and Hendriks assumed no product cost or performance impact and a 1 million per manufacturing site conversion cost which yielded an avoidance cost of 3.4 per tonne CO_2-eq. March (1998) assumed higher product and development costs, also with no performance impact, which resulted in an avoidance cost of 400 per tonne of CO_2. These two estimates differ by more than two orders of magnitude in direct emissions abatement costs with assumed equivalent indirect emissions. Table 4.4 summarizes emission abatement opportunities with increased application of HC-600a refrigerant in the three most common domestic refrigerator configurations. Estimates for manufacturing cost premiums, development costs and required implementation investments are also included. Emission abatement opportunities are based on Clodic and Palandre (2004).

The objective is to assess the total emissions from *direct* and *indirect* sources. HC-600a clearly has the advantage of minimizing *direct* GHG emissions. *Indirect* emissions can dominate overall results using some scenarios or assumptions. The energy consumption of basic HFC-134a and HC-600a refrigeration systems is similar. At issue is what product modifications are required or allowed when converting to an alternative refrigerant and what effect these modifications have on product efficiency and performance. This uncertainty is particularly applicable to larger, auto-defrost refrigerators where a trade-off between system efficiency and other product attributes necessary to maintain product safety is not obvious. The consequences of trends in consumer purchase choices and their influence on the rate of emissions reduction are also difficult to predict. LCCP and TEWI are powerful, complementary tools, but results are sensitive to input assumptions. Assumptions should be carefully validated to ensure they are representative of the specific sce-

Table 4.4. Domestic refrigeration, current status and abatement options.

Product Configuration		Cold Wall	Open Evaporator Roll Bond	No-Frost
Cooling capacity	From	60 W	60 W	120 W
	To	140 W	140 W	250 W
Refrigerant charge (HFC)	From	40 g	40 g	120 g
	To	170 g	170 g	180 g
Approximate percentage of sector refrigerant bank (160 kt) in configuration		20 units * 100 g average 18% of 160 kt	15 units * 100 g average 14% of 160 kt	50 units * 150 g average 68% of 160 kt
Approximate percentage of sector refrigerant emissions (8950 tonnes) in subsector		18% of 8950 tonnes	14% of 8950 tonnes	68% of 8950 tonnes
Predominant technology		HC-600a	HFC-134a	HFC-134a
Other commercialized technologies		HFC-134a, CFC-12	HC-600a, CFC-12	HC-600a, CFC-12
Low GWP technologies with fair or better than fair potential for replacement of HCFC/HFC in the markets		R-600a	HC-600a	HC-600a
Status of alternatives		Fully developed and in production	Fully developed and in production	Fully developed and in production
R-600a Mfg. Cost Premium		No Premium	3–5 US$	8–30 US$
Capital Investment		0	45–75 million US$	400–1500 million US$
Emission reduction		1432 tonnes	1253 tonnes	6086 tonnes

narios of interest.

Several investigators have analyzed total emission scenarios comparing HFC-134a and HC-600a for domestic refrigeration:

- An Arthur D. Little, Inc. LCCP study (ADL, 1999) estimated that approximately 14 grams (10% of initial charge) of HFC-134a would be the total net lifetime emissions from a domestic refrigerator in the USA regulatory environment. Using US power generation emission data, this equates to a 0.3% energy consumption increase over a typical 20-year product life;
- Ozone Operations Resource Group of the World Bank Report No. 5: 'The Status of Hydrocarbon and Other Flammable Alternatives Use in Domestic Refrigeration' (World Bank, 1993) cited TEWI assessments presented at the 1993 German National Refrigeration Congress in Nurnberg. Regarding the relative refrigerant selection effects, this TEWI analysis concluded that 'The *direct* contribution of HFC-134a to global warming … should not be given serious consideration within this rough estimate because it does not amount to more than a few percent of the *indirect* contribution caused by the energy consumption of the appliance' (Lotz, 1993).

4.2.8 Emission abatement opportunities

The following emission abatement opportunities are available for domestic refrigerators:

- Conversion to alternatives having reduced GWP: The refrigerant direct emission contribution ranges from less than 2% up to 100% of total emissions. Direct emissions of 100% reflect the condition where the power generation and distribution infrastructure has zero dependence on fossil fuel energy sources. Direct emissions favour HC-600a over HFC-134a. Regional regulatory and product liability considerations can hamper the viability of HC-600a application. Indirect emissions depend upon relative product energy efficiency. Thermodynamic cycle efficiencies of the alternatives are comparable. Product efficiency is dependent upon design attributes required to accommodate the flammability of HC-600a. There is no penalty with the cold-wall evaporator configurations common in Europe. Information concerning configurations commonly used for forced-convection, automatic-defrost products is limited or proprietary;
- Reduction of refrigerant leakage during service life: Annual leakage rates for the factory-sealed, hermetic systems in domestic units are typically less than 1%…This leakage typically drives service demand;
- Recovery of refrigerant during end-of-life disposal or during field repair: Approximately 5% of the installed base are retired each year. The annual service call rate is significantly less than that. Recovery efficiency is a critical variable;
- Reduction of indirect emissions through improved product energy efficiency: The indirect emission contribution for domestic refrigeration ranges from zero to more than 98% of total emissions. Current production refrigerators consume less than half the energy of the typically 20-year-old unit they replace. With a 5% yr^{-1} retirement rate, this translates to a 2.5% yr^{-1} improvement in indirect emissions from the installed base;
- Opportunities for reduced indirect emissions exist via improved product energy efficiency. The IEA energy efficiency policy profiles report (IEA, 2003) estimated the potential improvements to be 16–26%, dependent upon product configuration. Average cost inflation was estimated to be 23 (US$ 31) for manufacturing and 66 (US$ 88) for purchase. The report presents comparative Least Life Cycle Cost analyses for alternatives. Arthur D. Little conducted Life Cycle Climate Performance studies of HFC and other refrigerant alternatives (ADL, 2002). Their report gives heavy domestic refrigeration emphasis on the relative energy efficiency and Total Equivalent Warming Impact assessment of various blowing-agent alternatives.

4.3 Commercial refrigeration

Commercial Refrigeration is the part of the cold chain comprising equipment used by retail outlets for preparing, holding and displaying frozen and fresh food and beverages for customer purchase.

For commercial systems, two levels of temperature (medium temperature for preservation of fresh food and low temperature for frozen products) may imply the use of different refrigerants. Chilled food is maintained in the range 1°C–14°C but the evaporating temperature for the equipment varies between –15 °C and 5 °C dependent upon several factors: the type of product, the type of display case (closed or open) and the type of system (direct or indirect). Frozen products are kept at different temperatures (from –12 °C to –18 °C) depending on the country. Ice cream is kept at –18 to –20 °C. Usual evaporating temperatures are in the range of –30 to –40 °C.

On a global basis, commercial refrigeration is the refrigeration subsector with the largest refrigerant emissions calculated as CO_2 equivalents. These represent 40% of the total annual refrigerant emissions, see Table 11.5. Annual leakage rates higher than 30% of the system refrigerant charge are found when performing a top-down estimate (Clodic and Palandre, 2004; Palandre *et al*., 2004). This means that in an environment with an average energy mix, the refrigerant emissions might represent 60% of the total emissions of GHG resulting from system operation, the rest being indirect emissions caused by power production. This indicates how important emission reductions from this sector are.

There are five main practices in order to reduce direct GHG emissions:

1. A more widespread use of non-HFC refrigerants;
2. Leak-tight systems;
3. Lower refrigerant charge per unit of cooling capacity;
4. Recovery of refrigerant during service and end-of-life;
5. Reduced refrigeration capacity demand.

4.3.1 Sector background

Commercial refrigeration comprises three main types of equipment: stand-alone equipment, condensing units and full supermarket systems.

Stand-alone equipment consists of systems where all the components are integrated: wine coolers, beer coolers, ice cream freezers, beverage vending machines and all kinds of stand-alone display cases. This equipment is installed in small shops, train stations, schools, supermarkets and corporate buildings. Annual growth is significant. All types of stand-alone equipment are used intensively in industrialized countries and are the main form of commercial refrigeration in many developing countries. These systems tend to be less energy efficient per kW cooling power than the full supermarket systems described below. A main drawback to stand-alone units is the heat rejected to ambient air when placed indoors. Therefore, the heat must be removed by the building air conditioning system when there is no heating requirement.

Condensing units are used with small commercial equipment. They comprise one or two compressors, a condenser and a receiver which are normally located external to the sales area. The cooling equipment includes one or more display cases in the sales area and/or a small cold room for food storage. Condensing units are installed in specialized shops such as bakeries, butchers and convenience stores in industrialized countries, whilst in developing countries a typical application is the larger food retailers.

Full supermarket systems can be categorized by whether refrigerant evaporation occurs in the coolers, or whether a low-temperature secondary heat transfer fluid (HTF) that is cooled centrally is circulated in a closed loop to the display cabinets and cold stores. The first type is termed 'direct expansion' or direct system and the second type is termed indirect system. Direct systems have one less thermal resistance and no separate fluid pumping equipment, which gives them an inherent efficiency and cost advantage. The HTF circulated in an indirect system normally gains sensible heat, but may gain latent heat in the case of ice slurry or a volatile fluid like CO_2.

Many different designs of full supermarket systems can be found. *Centralized systems* consist of a central plant in the form of a series of compressors and condenser(s) located in a machinery room or an outside location. This provides refrigerant liquid or an HTF at the correct temperature levels to cabinets and cold stores in other parts of the building. Each rack of multiple compressors is usually associated with a single air-cooled condenser. Specific racks are dedicated to low-temperature or medium-temperature evaporators. The quantity of refrigerant is related to the system design, refrigerating capacity and refrigerant choice varies. The centralized systems can be either direct or indirect systems. Centralized direct systems constitute by far the largest category in use in supermarkets today. The size can vary from refrigerating capacities of about 20 kW to more than 1 MW. The centralized concept is flexible in order to utilize heat recovery when needed (Arias, 2002).

Distributed Systems are characterized by having smaller compressors and condensers close to or within the coolers, so that many sets of compressor/condenser units are distributed around the store. The compressors can be installed within the sales area with remote condensers. When they are installed as small packs with roof-mounted, air-cooled condensers, or as small packs adjacent to the sales area in conjunction with remote air-cooled condensers they are sometimes referred to as C*lose Coupled Systems*. The quantity of such units could range from just a few to upwards of 50 for a large supermarket. They are direct systems, but when installed inside the building that may employ a HTF, usually water, for collecting heat from the different units.

Hybrid systems cover a range of possibilities where there is a combination of types. An example is a variation of the distributed system approach, where low-temperature cabinets and cold stores comprise individual water-cooled condensing units, which are supplied by the medium-temperature HTF. Thus, in the indirect medium temperature section, the refrigerant charge is isolated mainly to the machinery room, whilst an HTF is circulated throughout the sales and storage areas at this temperature level.

In some countries, indirect, close-coupled, distributed and hybrid systems have been employed in increasing number in recent years because they offer the opportunity of a significant reduction in refrigerant charge. Additionally, with indirect systems the refrigerant charge is normally located in a controlled area, enabling the use of low-GWP refrigerants that are flammable and/or have higher toxicity. This approach has been adopted in certain European countries due to regulatory constraints on HCFCs and HFCs (Lundqvist, 2000). A review of possible system solutions is provided by Arias and Lundqvist (1999 and 2001). The close-coupled systems offer the advantages of low charge, multiple compressors and circuits for part load efficiency and redundancy, as well as the efficiency advantage of a direct system (Hundy, 1998).

4.3.2 Population/production

There is a lot of variation in the geographical distribution of commercial refrigeration systems, even in neighbouring countries, due to differing consumption habits, regulation of opening hours, leadership of brand names, state of the economy and governmental regulations.

A number of leading US and European manufacturers are expanding worldwide, especially into Eastern European countries and other countries with fast growing economies, such as: Argentina, Brazil, China, Indonesia, Mexico, Thailand and Tunisia. The growth of all types of commercial refrigerating systems in China is one of the most significant of the past 4 years. For example, the number of small supermarkets (average total sales area of about 380 m^2) has increased by a factor of six in the past 4 years.

Table 4.5 shows the average total sales area of supermarkets, which differs significantly per country. The 'hypermarket' concept of selling food, clothing and all types of household

Table 4.5. Typical sales areas of supermarkets in selected countries (UNEP, 2003).

	Brazil	China	France	Japan	USA
Average surface of supermarkets (m^2)	680	510	1500	1120	4000
Average surface of hypermarkets (m^2)	3500	6800	6000	8250	11,500

goods, is expanding worldwide.

Table 4.6 shows an estimate of supermarket and hypermarket populations and Table 4.7 an evaluation of the population of smaller commercial units.

It is only possible to evaluate the refrigerant quantities based on the number of supermarkets if additional data are used concerning the total sales area of fresh and frozen food and the type of refrigerating system. Nevertheless in terms of the number of supermarkets, China represents more than 30% of the total global population of supermarkets (UNEP, 2003).

For small commercial supermarkets, China represents about 40% of the total global population, with the exception of vending machines. The growth of vending machines is still very significant, especially in Europe (UNEP, 2003).

4.3.3 HFC and HCFC technologies, current usage and emissions

4.3.3.1 Refrigerant choices

Refrigerant choices for new equipment vary according to national regulations and preferences.

Europe: Following CFC phase out for new equipment and servicing in Europe, commercial refrigeration tended towards the use of HCFC-22 and HCFC-22 blends. However, in the Nordic countries, the period with HCFC-22 was very short, and HFCs such as R-404A became the preferred solution from 1996 onwards. Since 2000, European Regulation 2037/2000 (Official Journal, 2000) has prohibited HCFCs in all type of new refrigerating equipment. HFC-404A and HFC-507A are now the most commonly used refrigerants for larger capacity low- and medium-temperature systems, such as condensing units and all types of centralized systems. For stand-alone systems, HFC-134a is used for medium-temperature applications, while both HFC-134a and HFC-404A are used for low-temperature applications.

Table 4.6. Number of supermarkets and hypermarkets (UNEP, 2003).

	Number of Supermarkets	Number of Hypermarkets
EU	58,134	5410
Other Europe	8954	492
USA	40,203	2470
Other America	75,441	7287
China	101,200	100
Japan	14,663	1603
Other Asia	18,826	620
Africa, Oceania	4538	39
Total	**321,959**	**18,021**

Table 4.7. Evaluation of the number of items of commercial equipment (UNEP, 2003).

	Condensing Units	Hermetic groups in stand alone equipment	Vending Machines
EU	6,330,500	6,400,700	1,189,000
Other Europe	862,000	754,700	113,900
USA	247,500	217,400	8,807,900
Other America	3,321,300	2,430,600	411,800
China	13,000,000	12,316,600	385,000
Japan	2,216,000	2,470,600	2,954,500
Other Asia	5,750,400	5,750,600	758,200
Africa, Oceania	843,700	831,400	87,000
Total	**32,571,400**	**31,172,600**	**14,707,300**

Japan: In Japan where HCFCs are still permitted, a voluntary policy is followed by OEMs and more than one-third of new equipment employs HFCs, with the remainder using HCFC-22. Typically, HFC-407C is used for medium temperature and HFC-404A for low temperature in all categories of commercial systems.

USA and Russia: In the USA, HCFC-22 and HCFC-22 blends are commonly used in existing systems, primarily for medium-temperature applications. HCFC-22 continues to dominate new supermarket systems, but HFC-404A and HFC-507A are becoming more widely used. HFC-404A and HFC-134a are used in new stand-alone equipment. These trends are also seen in Russia, where alternatives include HFC-134a, HCFC-22 and HCFC-22 blends as well as HFC-404A in a broad range of commercial equipment.

Developing countries: Stand-alone equipment is the main form of commercial refrigeration in developing countries, with condensing units being used by larger food retailers. CFCs, HCFCs and HFCs are all being used, with trends towards HFCs HFC-134a and HFC-404A in the future.

In China, HCFC-22 and HFC-134a are the major refrigerants for commercial refrigeration, with R-404A showing rapid growth. Only limited amounts of CFC-12 and R-502 are in use, as most of the systems designed for these refrigerants have converted to HFC-134a and R-404A. HCFC blends have very little application, as Chinese regulatory groups prefer to switch directly to HFCs instead of using any transitional HCFC blends.

4.3.3.2 Emissions

Emission rates derived with a bottom-up approach suggest a global annual emissions rate from the commercial refrigeration sector of 30% of the refrigerant charge (leakage and non-recovery) (Palandre *et al.*, 2004). Expressed in CO_2 equivalents, commercial refrigeration represents 40% of total annual refrigerant emissions, see Table 4.1. The emission levels (including fugitive emissions, ruptures, emissions during servicing and at end-of-life) are generally very high, especially for supermarkets and hypermarkets. The larger the charge, the larger the average emission rate. This is due to the due to the very long pipes, the large numbers of fittings and valves, and the huge emissions when ruptures occur.

In the 1980s, the reported average commercial refrigeration emission rates for developed countries were in the range of 20–35% of refrigerant charge per year (Fischer *et al*., 1991; AEAT, 2003; Pedersen, 2003). The high emission rates were due to design, construction, installation and service practices being followed without an awareness of potential environmental impact. In some countries emissions from these systems have been decreasing due to industry efforts and governmental regulations with respect to refrigerant containment, recovery and usage record keeping, increased personnel training and certification, and improved service procedures, as well as increased attention for many system mechanical details including the reduction or elimination of threaded joints and a reduction in the number of joints in refrigerating systems.

Recent annualized emission rates in the range of 3–22% (average of 18%) were reported for 1700 supermarket systems in several European countries and the USA. The country-specific data and references are listed in Table 4.8. It may be concluded that if the emission estimates of Palandre *et al*. (2003 and 2004) are correct, the above-reported values of 3–22% must represent selected company data within countries that have a strong emphasis on emission reductions.

Emission rates vary considerably between equipment categories. Annual emission rates for the several categories are listed in Table 4.9. Individual system leak rates, however, can range from zero to over 100% yr^{-1}. It should also be noted that end-of-life recovery data are mostly not included, and therefore the annual average leakage rates may be 5–10% higher than the values given in the tables.

Table 4.8. Leakage rates of supermarket refrigeration systems.

Country	Year(s)	Annual Refrig. Loss	References
The Netherlands	1999	3.2	Hoogen *et al*., 2002
Germany	2000–2002	5-10%	Birndt *et al*., 2000; Haaf and Heinbokel, 2002
Denmark	2003	10%	Pedersen, 2003
Norway	2002–2003	14%	Bivens and Gage, 2004
Sweden	1993 1998 2001	14% 12.5% 10.4%	Bivens and Gage, 2004
United Kingdom	1998	14.4%	Radford, 1998
USA	2000–2002	13%, 18%, 19%, 22%	Bivens and Gage, 2004

Table 4.9. Indicative leakage rates from commercial refrigeration equipment categories found in the literature.

Category	Annual Refrigerant Loss	References
Stand-alone hermetic	≤1%	March, 1999; ADL, 2002
Small condensing unit	8–10%	March, 1999; AEAT, 2003
Centralized direct (DX)	3–22%	Several; see main text
Distributed	4%	ADL, 2002
Indirect (secondary loop)	2–4%	ADL, 2002

It is important to note that in certain cases, data collection should be considered in context. Some of the base data used in emission and emission projection studies has been collated from telephone interviews, and other similar techniques, from historical reports. This reliance on anecdotal data may suggest underestimated emissions, since both the end-users and refrigeration contractors have an interest in reporting low values because of exposure of poor practices and the threat of restrictive legislation.

As well as measures designed to decrease emissions, there are also drivers – typically at field level – that inhibit emission reduction and must be addressed at a policy level. These include partial success in finding system leaks, end-users employing contractors on an 'as-the-need-arises' basis rather than a preventative basis, additional attendance time for refrigerant recovery and leak testing, and a financial incentive for contractors to sell more refrigerant to the end-user.

There have been important observations on system emission characteristics and how emission reductions have been accomplished. Some are listed below.

In the Netherlands, emissions have been significantly reduced through national mandatory regulations established in 1992 for CFCs, HCFCs and HFCs. These measures have been assisted by an industry supported certification model (STEK, which is the abbreviation for the institution for certification of practices for installation companies in the refrigeration business). Elements of the regulation are detailed by Gerwen and Verwoerd (1998), and include the technical requirements to improve tightness, system commissioning to include pressure and leakage tests, refrigerant record keeping, periodic system-leak tightness inspections, and maintenance and installation work by certified companies and servicing personnel (Gerwen and Verwoerd, 1998). The STEK organization was founded in 1991 to promote competency in the handling of refrigerants and to reduce refrigerant emissions. STEK is responsible for company certification, personnel certification and the setting-up of training courses.

The success of the Dutch regulations and the STEK organization in reducing refrigerant emissions was demonstrated by the results from a detailed study in 1999 of emission data from the refrigeration and air conditioning sectors. For commercial refrigeration, annual refrigerant emissions (emissions during leakage plus disposal) as low as 3.2% of the total bank of refrigerant contained in this sector were reported (Hoogen and Ree, 2002).

In Germany, the report by Birndt *et al*. (2000) found that no leaks were identified in 40.3% of the systems, 14.4% of the leaks contributed to 85% of the refrigerant loss and 83% of the leaks occurred in the assembly joints. The report by Haaf and Heinbokel (2002) was on R-404A systems in medium- and low-temperature supermarket refrigeration. Data was taken on systems installed after 1995 with improved technologies for leak tightness, plus a reduction of refrigerant fill quantities by 15%. Annual leakage rates were determined to be 5% of charge, which represented a 10% reduction on the level reported in previous years.

The data from Sweden showed annual refrigerant losses decreasing from 14% in 1993 to 10.4% in 2002 (Bivens and Gage, 2004), with the lower emissions being attributed, in part, to an increased application of indirect cooling systems with reduced refrigerant charges in supermarkets.

A set of 2000–2001 USA emissions data were available for 223 supermarkets in the California South Coast Air Quality Management District (Los Angeles area). The data were reported in system charge sizes from 23 kg up to 1285 kg. Over the two-year period, 77% of the smaller charge size systems (23−137 kg) required no refrigerant additions, 65% of the medium charge size systems (138−455 kg) required no refrigerant additions and 44% of the larger charge size systems (456−1285 kg) required no refrigerant additions. These are the outcomes expected, based on larger charge size systems having longer piping runs, more assembly joints, more valves and more opportunities for refrigerant leakage. For the 223 supermarkets, total averaged refrigerant emission rates were 13% of charge in 2000, and 19% in 2001 (Bivens and Gage, 2004).

The data from Germany and the USA indicate that, since the average emission rates include systems with no emissions, the leaking systems have higher loss rates than the averages. This amplifies the importance of monitoring refrigerant charge using sight glasses and liquid levels, and of periodic checking with leak detectors. These both represent a significant opportunity for identifying and repairing high leakage rate sources. Procedures for emission reduction have been developed by ANSI/ASHRAE, 2002.

The trend away from the ozone-depleting CFCs and HCFCs, and towards an increased use of HFCs means, that despite lower leakage rates, HFC leakage from refrigeration is set to increase considerably. For example in Europe, a 50% cut in leakage rates due to the initiation of STEK-like programmes in every member state would result in emissions rising from 2.5–4.3 Mtonnes CO_2-eq in 1995 to around 30 Mtonnes CO_2-eq in 2010, instead of 45 Mtonnes CO_2-eq under a business-as-usual scenario (Harnisch and Hendriks, 2000; Enviros, 2003).

The continuing collection of reliable emissions data is an important factor in getting a clear picture of the leakage situation and thereby establishing progress in the reduction of refrigerant emissions. Palandre *et al*. (2003 and 2004) and US EPA (2004) report two global programmes for the collection of such data. Data from the Clodic and Palandre (2004) permits the calculation of the worldwide commercial refrigeration emission rate for the year 2002 and this amounted to 30% of the commercial refrigeration systems inventory. The US EPA model information also permits the calculation of a potential 20−30% reduction business-as-usual HFC emissions from commercial refrigeration in the year 2015, by applying abatement options that require a more aggressive leak detection and repair and the increased use of distributed and indirect systems (Bivens and Gage, 2004).

4.3.4 Non-HFC technologies (vapour compression)

A number of HCs, ammonia and CO_2 systems of different refrigerating capacities have been installed in various European countries during the past 5 years. A few examples of these are now given.

4.3.4.1 Stand-alone equipment and condensing units

Some well-established beverage companies and ice cream manufacturers have recently stated (2000−2001) that by 2004 they will no longer purchase new equipment that uses HFCs in their refrigerant systems, provided that alternative refrigerants or technologies become available at an acceptable cost. HCs, CO_2 and Stirling technology are being evaluated by one of the companies (Coca Cola, 2002). The HFC-free strategy of the companies were confirmed during June 2004 (RefNat, 2004).

4.3.4.1.1 Hydrocarbons

Various companies in several countries have developed vending machines and small commercial equipment using HCs. The equipment uses HC-600a, HC-290 and HC-based blends. Limitations on charge sizes are specified by safety standards (e.g. EN 378, IEC 60335-2-89), where maximum amounts per circuit are 2.5 kg, 1.5 kg and 150 g, dependent on the application. Nevertheless, HC charges tend to be about 50% less than equivalent HFCs and HCFCs due to lower densities which minimize the impact of such limits. Recent developments with charge-reduction techniques (Hoehne and Hrnjak, 2004) suggest that charges for future systems will become even less. Christensen (2004) reports on the experience with stand-alone equipment installed in a restaurant in Denmark. Results from a detailed quantitative risk assessment model that examined the safety of hydrocarbons in commercial refrigeration systems are reported in Colbourne and Suen (2004).

4.3.4.1.2 Carbon dioxide (CO_2)

CO_2 is being evaluated by a European company interested in developing stand-alone equipment with a direct expansion CO_2 system (Christensen, 1999) and is also one of the refrigerants being evaluated by Coca Cola (2002). The company confirmed their HFC-free strategy in June 2004 and announced that CO_2-based refrigeration is their current choice for future equipment (Coca Cola, 2004). R&D activities for CO_2-based solutions have also been announced by another company (McDonalds, 2004).

4.3.4.2 Full supermarket systems

4.3.4.2.1 Direct systems

CO_2 direct systems
CO_2 is non-flammable, non-toxic and has a GWP value of only 1. It is therefore highly suited for use in direct refrigeration systems, as long as acceptable energy efficiency can be achieved at a reasonable cost. There are two basic types of CO_2 direct systems using only CO_2 as a refrigerant and cascade systems.

Direct systems using only CO_2 as a refrigerant have been developed with a transcritical/subcritical cycle, depending on ambient temperature, for both low- and medium-temperature refrigeration are developed. In addition to giving a totally non-HFC solution, reduced pipe diameters due to higher pressures, good heat transfer characteristics of CO_2 and the possibility to obtain energy efficient heat recovery can be mentioned. Five medium-sized supermarkets have been installed with this concept by the beginning of June 2004, in addition to some smaller field test systems (Girotto and Nekså, 2002; Girotto *et al*. 2003; Girotto *et al*. 2004).

Cascade systems are being developed with CO_2 at the low-temperature stage associated with ammonia or other refrigerants (R-404A for example) at the medium-temperature stage. Several of these systems have been installed in the field and are currently being evaluated in different European countries. Haaf and Heinbokel (2003) have described 33 such CO_2 cascade systems from one manufacturer that were in service in 2003. It is emphasized that this technology could receive widespread interest because it has also been developed for the food industry (Rolfsmann, 1999; Christensen, 1999).

In addition to these two options, a third distributed system concept was described by Nekså *et al*. (1998). Self-contained display cabinets, each with CO_2 refrigeration units, are connected to a hydronic heat-recovery circuit that heats service water and buildings. A large temperature glide in the hydronic circuit, typically 50–60 K, and a correspondingly low volume flow rate and small pipe dimensions can be achieved by using the transcritical CO_2 process. Waste heat with a high temperature (70–75^{o}C) is available for tap water and/or space heating. Excess heat is ejected to the ambient air.

The Institute of Refrigeration in London has released a 'Safety Code for Refrigerating Systems Utilizing Carbon Dioxide'. This contains a lot of relevant information despite much of the focus being on larger capacity industrial sized systems.

4.3.4.2.2 Indirect systems

Ammonia and hydrocarbons (HCs)
The quantity of ammonia can be 10% of the usual HFC refrigerant charge, due to indirect system design and the thermodynamic properties such as latent heat vaporization and liquid density (Presotto and Süffert, 2001). For HCs, the refrigerant charge is typically 10% of the direct system HFC reference charge (Baxter, 2003a,b).

In Northern Europe, ammonia or HCs (including HC-1270, HC-290 and HC-290/170 blends) have been used as refrigerants for the same type of indirect systems. For safety purposes, the refrigerant circuits are either separated in a number of independent circuits to limit the charge of each system or a number of independent chiller circuits are used (Powell *et al*., 2000).

Heat transfer fluids (HTF)
The HTFs used in indirect systems require special attention, especially at low temperatures where pumping power may be excessive. The choice of the correct HTF to obtain the desired energy efficiency is critical and a handbook on fluid property data is available from IIR/IIF (Melinder, 1997).

CO_2 as a heat transfer fluid
For indirect systems, CO_2 can be used as either a standard HTF without phase change or as a two-phase HTF that partially evaporates in the display case evaporators and condenses in the primary heat exchanger.

At low temperatures, phase-changing CO_2 HTF shows promising results. Due to the viscosity constraint of other alternatives at low temperatures and the good heat transfer properties of CO_2, the use of CO_2 as a low-temperature HTF has received more consideration than the alternatives. When CO_2 is used with phase change, the diameter of the tubes can be significantly reduced, and the heat transfer in the display case heat-exchanger is far more effective. If the temperature can be maintained below –12°C, traditional technologies in which the tubes and heat exchanger are designed for a maximum operating pressure of 25 bar, are possible. About 50 such systems are in operation in Europe. Expansion vessels, cold finger concepts or simply using the cold stored in the goods, are possible alternatives for keeping the pressures within acceptable limits.

Ice slurry as a heat transfer fluid
An interesting new technology for medium temperature, which offers the possibility of energy storage and high-energy efficiency, is indirect systems that use ice slurry as the HTF. Research has been carried out in some pilot installations. A handbook is currently being developed by the International Institute of Refrigeration and several recent papers on various aspects of the technology are described in Egolf and Kauffeld (2005).

4.3.5 Not in-kind technologies (non-vapour compression)

There are very few examples of the successful implementation of 'not-in-kind' technologies in this sector. One possible example is the Stirling cycle. For low capacity, high-temperature lift applications in particular (>60 K), the Stirling cycle may reach competitive COP values. Although Stirling systems have been developed, cost is still an issue (Lundqvist 1993; Kagawa, 2000). This technology is also being evaluated for display cabinets (Coca Cola, 2002). Another interesting recent technology is thermoacoustic refrigeration (Poese, 2004).

Heat-driven cycles have not found their way into commercial refrigeration. The use of heat-driven cycles such as absorption and adsorption in supermarkets have been discussed in literature (Maidment and Tozer, 2002). Some attempts with solar-driven refrigeration for fresh food handling have also been developed and tested (Pridasawas and Lundqvist, 2003). The use of sorption technologies for dehumidification, thus lowering the cooling load on display cabinets, is an interesting option.

4.3.6 Relevant practices to reduce refrigerant emissions

As stated at the beginning of this section, several abatement strategies can be used to reduce refrigerant greenhouse gas emissions. New design ideas have been mentioned throughout the chapter and these may be summarized as a general trend towards lower refrigerant charge, using direct or indirect systems, and the use of non-HFC refrigerants such as ammonia, CO_2 or HCs. These options should be considered on the basis of a balanced evaluation of refrigerant emission reductions, initial investment costs, safety, operating costs and energy consumption.

The European Commission has proposed a new regulation to reduce the emissions of fluorinated greenhouse gases, including HFCs from refrigeration equipment. In addition to a general obligation to avoid leakage, installations with over 3 kg of charge will require at least annual inspections, and a refrigerant detector will be required for systems over 300 kg. Reports will also be required for the import and export of refrigerants, and end-of-life recovery, recycling or destruction of the refrigerant. Additional information on country initiatives for refrigerant conservation is described in the 2002 UNEP TOC report, Sections 4.7 and 10.1 to 10.9 (UNEP, 2003).

Several programmes, for example in the Netherlands and Sweden, have shown good results with respect to leakage mitigation for existing plants. A common denominator has been a combination of regulation, education and accreditation of service personnel (STEK, 2001). In Denmark and Norway a tax on refrigerants in proportion to their GWP value has proven successful in curbing emissions and promoting systems that use non-HFC refrigerants.

A reduction of the refrigeration capacity demand, for example by using better insulation and closed rather than open cabinets, might indirectly reduce refrigerant emissions, but also the power consumption of a supermarket. Design integration with air-conditioning and heating systems are also important measures in this respect.

An interesting development in new design tools for supermarkets, opens up new possibilities for improving the design of systems using an LCC perspective, which favours more energy efficient systems with lower operating costs (Baxter, 2003a,b).

4.3.7 Comparison of HFC and non-HFC technologies

The current rapid developments in the subsector are moving the targets for energy efficiency, charge reduction and cost. This makes a comparison between technologies difficult. Furthermore, the relatively complex links between energy efficiency, emissions and the costs of systems and their maintenance means that it sis difficult to make fair comparisons.

4.3.7.1 Energy consumption of supermarkets

Depending on the size of the supermarket, the refrigeration equipment energy consumption represents between 35–50% of the total energy consumption of the store (Lundqvist, 2000). This ratio depends on a number of factors such as lighting, air conditioning, and so forth. For typical smaller supermarkets of around 2000 m^2, refrigeration represents between 40–50% of the total energy consumption and for even smaller stores it could be up to 65%.

New, high-efficiency commercial supermarkets have been designed in some European countries and the USA by using a number of efficient technologies. These references can be seen as prototypes and one example from UK presents energy consumption figures which are a factor of two lower compared to usual stores (Baxter, 2003a,b). Most examples however show reductions of between 10–20%.

The high annual growth rate of stand-alone equipment, which tends to be less energy efficient per kW cooling power than centralized systems, should be addressed. Integrating heat rejection from the individual cabinets in a water circuit may be one way of obtaining improved energy efficiency. Excessive heat rejection within the store might also lead to an increased demand for air conditioning, further increasing the energy demand.

4.3.7.2 Energy efficiency of direct systems

The energy efficiency of refrigeration systems first of all depends on the temperature levels for which refrigeration is provided and on the global design of the system. Measurements of system efficiency can be found in the literature, for example in UNEP (2003). However, comparisons of different systems are often difficult because the boundary conditions are rarely comparable.

Potential energy-saving measures may be divided into four different groups: advanced system solutions, utilization of natural cold (free cooling), energy-efficient equipment (display cases, efficient illumination, night curtains, etc.) and indoor climate/building-related measures. Energy-efficient illumination has the double effect of reducing loads on display cases as well as direct electric consumption. Heat recovery from condensers is sometimes preferred in cold climates but internal heat generation from plug-in units and illumination is often enough to heat the premises (Lundqvist, 2000).

The refrigeration system efficiency also depends on a number of parameters: pressure losses related to the circuit length, system control and the seasonal variation of the outside temperature. For a number of global companies energy consumption, and with this the energy efficiency of refrigerating systems, has become an important issue, especially in countries where electricity prices are high. One approach to energy savings is to utilize 'floating condensing temperature' in which the condensing temperature follows ambient temperature. The issue of climate change and the desire to reduce GHG emissions has also heightened the interest in increasing the energy efficiency.

4.3.7.3 Energy efficiency and cost of indirect systems

The evaluation of the additional energy consumption related to indirect systems is an ongoing process. Direct field comparisons between direct and indirect systems are difficult (Lundqvist, 2000; Baxter, 2003a). Moreover, the main driver for centralized systems is initial cost. Due to the design of heat exchangers in display cases (especially medium-temperature, open-type) the performances of some indirect systems can be equal or even slightly better than direct systems (Baxter, 2003a). For low temperatures, the energy penalty can be substantial depending on the design.

On the other hand, the relative energy consumption of indirect systems – compared to conventional direct expansion systems – can show an increased energy consumption of up to 15%. Conclusions can only be drawn if reference lines for the energy consumption of centralized systems are plotted in which the origin of energy inefficiencies are apparent. Due to the extra temperature difference required, inherently indirect systems should give higher energy consumptions compared to direct systems. Recent practical experiences and experimental studies (Mao *et al*., 1998; Mao and Hrnjak, 1999; Lindborg, 2000; Baxter, 2003a,b), however, indicate that well-designed indirect systems may have energy efficiencies approaching those of good direct systems. Further research is clearly needed to clarify the reasons for this. More efficient defrost, better part-load characteristics, better expansion device performance and more reliable systems are believed to contribute to indirect system energy efficiency. The costs might be 10–30% higher, but these can potentially be reduced (Yang, 2001; Christensen and Bertilsen, 2003).

4.3.7.4 Energy efficiency and cost of ammonia systems

There are several indirect systems in operation that are successfully using ammonia as the primary refrigerant (Haaf and Heinbokel, 2002). As ammonia is toxic and may create panic due to the strong smell at low concentrations appropriate safety precautions are required. Excellent energy efficiency can be achieved with properly-designed systems. The drawbacks for ammonia systems are limited service competence (Lindborg, 2002) and higher initial costs, typically 20–30%. A life-cycle cost evaluation is therefore required.

4.3.7.5 Energy efficiency and cost of hydrocarbon systems

Full supermarket systems using hydrocarbons in an indirect design have been installed in several European countries. A dedicated ventilation system (if installed in a machine room), gas detectors, gas-tight electric equipment and so forth have been installed for safety reasons. The use of hydrocarbons has increased the R&D effort to significantly minimize refrigerant charge. A small prototype system of approximately 4 kW cooling capacity using 150 g of HC-290 and micro-channel heat exchanger technology has been demonstrated by Fernando *et. al*. (2003). Cost is still an issue, typically up to 30% higher, but further development is expected to reduce costs. HC-290 and HC-1270 are excellent refrigerants from a thermodynamic point of view and equipment design is relatively straightforward. The availability of some standard components is still limited, but to a certain extent the hydrocarbon systems can use the same type of system components as HFC systems. Cascade systems with HC-290 and CO_2 for full supermarket systems were reported to have an energy efficiency equal to conventional direct system design (Baxter, 2003a,b).

For stand-alone equipment and condensing units, several references report a higher efficiency of HC refrigerants systems compared to equivalent systems with HFCs, for example Elefsen *et al*. (2002). Others claim that higher efficiency can be achieved with HFC systems, if the extra costs used for the safety precautions of HC systems are used to improve system efficiency of the HFC system (Hwang *et al*., 2004).

4.3.7.6 Energy efficiency and cost of CO_2 systems

Centralized CO_2 direct systems for both medium and low temperature, operating in either transcritical or subcritical cycle dependent on the ambient temperature, are reported to require about 10% higher energy consumption than a state-of-the-art R-404A direct system (Girotto *et al*., 2003 and 2004). Several measures for improvements have however been identified. The cost is reported to be about 10–20% higher than for direct expansion R-404A systems and this difference is mainly due to components produced in small series.

Haaf and Heinbokel (2003), report energy consumption and investment costs for R-404A/CO_2 cascade systems that are similar to R-404A direct systems. This is due to the fact that components for CO_2 cascade systems are more similar to R-404A components (maximum pressure 40 bar), allowing more standard components to be used. Girotto *et al*. (2004) report higher costs for cascade systems (see also comment about HC-290/CO_2 above).

4.3.7.7 Energy efficiency and cost of HFC systems with reduced emissions

Ongoing R&D efforts to minimize refrigerant charge without compromizing energy efficiency are applicable to HFC refrigerants as well. The standard approach to charge minimization is to use no receiver or hermetic compressors and to keep piping as short as possible. Tight systems require brazed joints and these are most reliably made when systems are factory assembled. The potential for charge reduction is illustrated by Fernando *et al*. (2003). They present HC systems using as little as 150 g refrigerant for a 5 kW domestic heat pump. The density of HFC refrigerant is approximately twice that of HC and therefore a comparable system using 300 g of HFC refrigerant is within reach, if further heat exchanger development is undertaken. More complex cycles are another way of improving systems. Beeton and Pham (2003), report a 41% capacity increase and a 20% efficiency increase for low-temperature economizer systems using R-404A and R-410A.

4.3.8 Comparison of LCCP and mitigation costs

The number of publications that give TEWI or LCCP data for commercial refrigeration systems is limited but is growing rapidly. Harnisch *et. al*. (2003) calculated the LCCP for several different types of full supermarket refrigeration systems in Germany. They used a straightforward model which took production, emissions and energy usage into account. CO_2 emissions from power production were calculated using an average emission factor of 0.58 kg CO_2 kWh^{-1}. The transparent method to evaluate the various systems allows sensitivity analyses to be performed using other literature references referred to in this report. Table 4.10 presents characteristic figures from Harnisch *et. al*. (2003) and compares these to calculated results based on representative data from other literature references.

The data used for the table are selected as follows: The 30% emission is based on Palandre *et al*., 2004 and the 11.5% and 6.5% emission scenarios are based on Harnisch *et al*. (2003), Bivens and Gage (2004) Baxter (2003a) and ADL (2002). The 11.5% and 6.5% emissions represent 10% and 5% emissions yr^{-1}, with a 15% end-of-life recovery loss apportioned over a 10-year lifetime. Energy consumption figures are extracted from Harnisch *et al*. (2003), Haaf and Heinbokel (2002), Girotto *et al*. (2003) and Baxter (2003b). It is clear that several different alternatives result in reductions in CO_2 equivalent emissions of the same order of magnitude. The same applies for an HFC alternative, if the annual emission rate can be as low as 5%. If a 5% leakage is possible, the dominating contribution from most systems is an indirect effect due to power production.

Supermarket system and mitigation cost estimates are scarce. Harnich *et al*. (2003) give data for German supermarkets with costs ranging from 20–280 US$ per tCO_2–eq mitigated. The lowest values are given for a system using direct expansion CO_2 for low temperature and direct expansion with R-404A for high temperature. Mitigation costs are estimated using a 10% leakage rate and a 1.5 % recovery loss, with a 10-year lifetime and a discount rate of 10% to reflect commercial decision-making. An average cost of 100 US$ m^{-2} of supermarket area is used as a baseline for cost estimates. This figure is confirmed by Sherwood (1999) who reports on cost figures for a 3200 m^2 supermarket in the USA.

Using this data with a broader range of leakage rates and estimated costs, significantly reduces the typical mitigation costs per tonne of CO_2 suggested by Harnisch *et al*. (2003) but also expands the total range to values of 10–300 US$ per tonne CO_2-eq mitigated.

Additional mitigation costs for the various systems suggested in the chapter have not been calculated. Cost estimates for various technologies given in the literature suggest a cost increase between 0 and 30% for alterative technologies compared to a baseline, full supermarket, direct system using R-404A as refrigerant. Some detailed figures are already given under each section and a general summary is given for each technology in Table 4.11.

Table 4.10. LCCP values of full supermarket systems.

Configuration	Refrigerant Emissions % charge yr^{-1}	Energy Consumption	LCCP, in tCO_2-eq yr^{-1} Indirect	Direct	Total
Direct Expansion (DX)	30%	baseline	122	183	305

* Alternatives in these categories have been commercialized, but since the current number of systems are limited, they are only referenced as options below

In this report energy efficiency has been treated as relative changes in energy usage for several recent types of systems, the main purpose of which is to mitigate emissions, see also Table 4.11. However, the systems investigated are based on current technological standards for components such as heat exchangers, compressors and so forth. No attempts have been made to predict the future energy-saving potential in commercial refrigeration applications if future possible improvements are achieved. Several possibilities for reducing the energy consumption of refrigeration systems exists, but in principle most of these may be applied irrespective of the refrigerant used in the system. These options may also lead to negative mitigation costs, as for instance reported in Godwin (2004) and March (1998).

The authors firmly believe that the ongoing technical development of components and systems together with various energy-saving measures (such as heat recovery, more efficient compressors and display cases, larger heat exchangers, floating condensation, energy efficient buildings and so forth) may lower supermarket energy consumption considerably.

4.4 Food processing and cold storage

4.4.1 Introduction

Food processing and cold storage is one of the important applications of refrigeration, and is aimed at preserving and distributing food whilst keeping its nutrients intact. This application of refrigeration is very significant in terms of size and economic importance, and this also applies to developing countries. Food processing includes many subsectors such as dairy products, ice cream, meat processing, poultry processing, fish processing, abattoirs, fruit & vegetable processing, coffee, cocoa, chocolate & sugar confectionery, grain, bread & flour confectionery & biscuits, vegetable, animal oils & fats, miscellaneous foods, breweries and soft drinks (March, 1996).

The annual global consumption of frozen foods is about 30 Mtonnes yr^{-1}. Over the past decade, consumption has increased by 50% and it is still growing. The USA accounts for more than half of the consumption, with more than 63 kg per capita. The average figure for the European Union (EU) is 25 kg and for Japan 16 kg. The amount of chilled food is about 10–12 times greater than the supply of frozen products, giving a total volume of refrigerated food of around 350 Mtonnes yr^{-1} (1995) with an estimated annual growth of 5% (IIR, 1996; UNEP, 2003). Like chilling and freezing, food processing is also of growing importance in developing countries. This is partly due to the treatment of high-value food products for export. Even in 1984, about half of the fish landed in developing countries (more than 15 Mtonnes) was refrigerated at certain stages of processing, storage or transport (UNEP, 1998). The estimated annual growth rate in food processing between 1996 and 2002 was 4% in developed countries and 7% in developing countries (UNEP, 2003).

Frozen food in long term-storage is generally kept at −15°C to −30°C, while −30°C to −35 °C is typical for the freezing process. In so-called 'super-freezers', the product is kept at −50°C. Chilled products are cooled and stored at temperatures from −1°C to 10°C.

The majority of refrigerating systems for food processing and cold storage are based on reciprocating and screw compressors. System size may vary from cold stores of 3 kW cooling demand to large processing plants requiring several MW of cooling. Reciprocating compressors are most frequently used in the lower capacity range, whereas screw compressors are common in larger systems (UNEP, 2003).

4.4.2 Technical options

Most of the refrigerating systems used for food processing and cold storage are based on vapour compression systems of the direct type, with the refrigerant distributed to heat exchangers in the space or apparatus to be refrigerated. Such systems are generally custom-made and erected on site. Indirect systems with liquid chiller or ice banks are also commonly used in the food processing industry for fruit and vegetable packing, meat processing and so forth. Ammonia, HCFC-22, R-502 and CFC-12 are the refrigerants historically used. The current technical options are HFCs, and non-fluorocarbons refrigerants such as ammonia, CO_2 and hydrocarbons (UNEP, 2003). Table 4.12 gives the main refrigerant technical options along with percentage annual emissions for food processing, cold storage and industrial refrigeration applications (Clodic and Palandre, 2004).

4.4.3 HFC technologies

HFC refrigerants are being replaced by place of CFC-12, R-502 and HCFC-22 in certain regions. The preferred HFCs for food processing and cold storage applications are HFC-134a, HFC blends with insignificant temperature glide such as R-404A, R-410A and azeotropic blends like R-507A. The HFC blend R-407C is also finding application as a replacement for HCFC-22.

HFC-134a has completely replaced CFC-12 in various applications of refrigeration. However, CFC-12 was not widely used in food processing and cold storage because it requires considerably greater compressor swept volume than HCFC-22 or ammonia to produce the same refrigerating effect. There is limited use of HFC-134a in this subsector.

R-404A, R-407C and R-507A are currently the most used HFCs for cold storage and food processing. These blends are preferred to HFC-134a due to the higher volumetric capacity

Table 4.12. Food processing, cold storage and industrial refrigeration (2002).

	CFCs (CFC-12 and R-502)[(1)]	HCFC-22	NH_3	HFCs (HFC-134a, R-404A, R-507A, R-410A)[(1)]
Cooling Capacity	25 kW–1000 kW	25 kW–30 MW	25 kW–30 MW	25 kW–1000 kW
Emissions, t yr^{-1}	9500	23,500	17,700	1900
Refrigerant in bank, tonnes	48,500	127,500	105,300	16,200
Emissions % yr^{-1}	20%	16%	17%	12%

[(1)] See Annex V for an overview of refrigerant designations for blends of compounds.

and lower system cost (UNEP, 1998). In spite of minor temperature glides, R-404A has proven to be applicable even in flooded systems (Barreau *et al*., 1996). R-404A and R-507A are the primary replacements for R-502. The coefficients of performance are comparable to R-502 but significantly lower compared to those of NH_3 and HCFC-22, especially at high condensing temperatures. Air-cooled condensers should be avoided as far as possible. The liquid should be subcooled to achieve optimal efficiencies and high cost-effectiveness for systems with R-404A and R-507A. In chill applications it may also be necessary to add significant superheat to the suction gas in order to avoid refrigerant condensation in the oil separator (UNEP, 2003).

R-410A is also one of the HFC blends which is expected to gain a market share in food processing and cold storage applications due to the lower compressor swept volume requirements in comparison to other refrigerants (except to CO_2). The compressor efficiencies, pressure drop in suction lines and heat transfer efficiency will benefit from high system pressure (UNEP, 1998). Due to the high volumetric capacity (40% above that of HCFC-22), R-410A compressor efficiency has been reported to be higher than with HCFC-22 (Meurer and König, 1999). R-410A can have system energy efficiency similar to that of ammonia and HCFC-22 and significantly higher than that of R-404A and R-507A for evaporation temperatures down to –40°C.

4.4.4 Non-HFC technologies

Ammonia

Ammonia is one of the leading refrigerants for food processing and cold storage applications. The current market share in several European countries, especially in the north, is estimated to be up to 80% (UNEP, 1998). In the USA ammonia has approximately 90% market share in systems of 100 kW cooling capacity and above in custom-engineered process use (IIR, 1996).

Recently designed ammonia-based systems have improved quality with respect to design, use of low-temperature materials and better welding procedures. Low charge is another positive development. However, more important is that these factory made units or systems represent a new level of quality improvement. These systems are not likely to break or release their charge in another way unless there is a human error or direct physical damage. Charge reduction has been achieved by using plate-type heat exchangers or direct expansion tube and shell evaporators (UNEP, 2003).

HCFC-22

The use of HCFC-22 is declining in food processing and cold storage applications in most developed countries. In Europe some of the end-users prefer ammonia and CO_2 wherever possible, whereas HCFC-22 has become the most common refrigerant to replace CFCs in food processing and cold storage in the USA (UNEP, 2003).

In developing countries, HCFC-22 is still an important replacement refrigerant for CFCs in new systems, as from a technical point of view HCFC-22 could replace CFC-12 and CFC-502 in new systems. Another important consideration in developing countries is that HCFC-22 will be available for service for the full system lifetime.

Hydrocarbons (HCs)

A growing market for low charge hydrocarbon systems has been observed in some European countries. So far market shares are small, which may be due to the flammability of these refrigerants. Nevertheless, several manufacturers have developed a wide range of products.

Commercialized refrigerants used in food processing and cold storage applications include HC-290, HC-1270 and HC-290/600a blends, although pure substances will be preferred in flooded systems. All of these refrigerants possess vapour pressures very similar to those of HCFC-22 and R-502. System performance with regard to system efficiency is comparable to, and in some cases even superior to, that of the halocarbons. Hydrocarbons are soluble with all lubricants, and compatible with materials such as metals and elastomers that are traditionally used in refrigeration equipment. As long as safety aspects are duly considered, standard refrigeration practice for HCFCs and CFCs can be used without major system detriment to system integrity (UNEP, 1998, 2003).

Given the flammability concerns, design considerations as detailed in the relevant safety standards should be adhered to. Additional safety measures should be considered for repairing and servicing. Several national and European standards permit the use of HCs in industrial applications and lay down specific safety requirements (ACRIB, 2001; UNEP, 2003).

Carbon dioxide

Carbon dioxide technology for low temperatures such as food freezing is an attractive alternative, especially in cascade systems with CO_2 in lower stage and ammonia in the upper stage, due to its excellent thermophysical properties along with zero ODP and negligible GWP.

Further, the volumetric refrigerating capacity of CO_2 is five times higher than HFC-410A and eight times higher than for ammonia and other refrigerants. This means that the size of most of the components in the system can be reduced (Roth and König, 2001). However, application of CO_2 places a limitation on evaporating temperatures due to the triple point (the temperature and pressure at which liquid, solid and gaseous CO_2 are in equilibrium) of –56.6°C at 0.52 MPa.

CO_2 technology has been applied to food processing and cold storage, both as a conventional and as secondary refrigerant. It is expected that CO_2 market share will increase in this subsector, especially for freezing and frozen food storage.

Not-in-kind technologies

There are some not-in-kind (non-vapour compression) technologies like air cycle, vapour absorption technology and compression-absorption technology which can be used for food processing and cold storage applications. Vapour absorption technology is well-established whereas compression-absorption technology is still under development.

Vapour absorption technology
Vapour absorption is a tried and tested technology. Absorption technologies are a viable alternative to vapour compression technology wherever low cost residual thermal energy is available. The most commonly used working fluid in food processing and cold storage applications is ammonia with water as the absorbent. The use of absorption technology is often limited to sites that can utilize waste heat, such as co-generation systems.

Compression-absorption technology
Compression-absorption technology has been developed by combining features of the vapour-compression and vapour-absorption cycles. About 20 compression-absorption systems on both a laboratory and full-scale have been developed and tested successfully so far. Various analytical and experimental studies have shown that the COP of compression-absorption systems is comparable to that of vapour compression systems. However, this system suffers from the inherent disadvantage of being capital intensive in nature. The technology is still at developmental stage (Pratihar *et al*., 2001, Ferreira and Zaytsev, 2002).

4.4.5 Factors affecting emission reduction

Design aspects
The refrigeration system design plays a vital role in minimizing the refrigerant emissions. A proper system design including heat exchangers, evaporators and condensers can minimize the charge quantity and hence reduce the potential amount of emissions. Every effort should be made to design tight systems, which will not leak during the system's lifespan. The potential for leakage is first affected by the design of the system; therefore designs must also minimize the service requirements that lead to opening the system. Further, a good design and the proper manufacturing of a refrigerating system determine the containment of the refrigerant over the equipment's intended life. The use of leak tight valves is recommended to permit the removal of replaceable components from the cooling system. The design must also provide for future recovery, for instance by locating valves at the low point of the installation and at each vessel for efficient liquid refrigerant recovery (UNEP, 2003).

Minimizing charge
The goal of minimal refrigerant charge is common for all systems due to system and refrigerant costs. Normally the designer calculates the amount of charge. In large systems such as food processing and cold stores, very little attention was generally given to determining the full quantity of refrigerant charge for the equipment. Its quantity is not often known (except for small factory built units). Charging the refrigerant into the system is done on site to ensure stable running conditions.

Improved servicing practices
Servicing practices in refrigeration systems must be improved in order to reduce emissions. Topping-off cooling systems with refrigerants is a very common practice, especially for the large systems normally used in food processing and cold storage industry, which causes greater emissions of refrigerant. However in general, proper servicing has proven to be more expensive than topping-off refrigeration systems. It is therefore necessary to make end-users understand that their practice of topping-off the systems without fixing leaks must cease because of the increased emissions to the environment. The good service practices are preventive maintenance, tightness control and recovery during service and at disposal.

Installation
After proper designing of the system, installation is the main factor that leads to proper operation and containment during the useful life of the equipment. Tight joints and proper piping materials are required for this purpose. Proper cleaning of joints and evacuation to remove air and non-condensable gases will minimize the service requirements later on and results in reduced emissions. Careful system performance monitoring and leak checks should also be carried out during the first days of operation and on an ongoing basis. The initial checks also give the installer the opportunity to find manufacturing defects before the system becomes fully operational. The proper installation is critical for maximum containment over the life of the equipment (UNEP, 2003). The refrigeration system should be designed and erected according to refrigeration standards (e.g. EN378 (CEN, 2000/2001)) and current codes of good practice.

Recovery and recycling
The recovery and recycling of refrigerants is another important process that results in significant reductions in emissions. The purpose of recovery is to remove as much refrigerant as possible from a system in the shortest possible amount of time. For applications where maintenance operations require opening the circuit, the difference between deep recovery and 'normal recovery' can represent 3–5% of the initial charge (Clodic, 1997). However many countries have adopted final recovery vacuum requirements of 0.3 or 0.6 atm absolute depending on the size of the cooling system and saturation pressure of the refrigerant. This provides a recovery rate of 92–97% of the refrigerant (UNEP, 1998).

The recovered fluorocarbon refrigerants can be recycled and then reused. The process of recycling is expected to remove oil, acid, particulate, moisture and non-condensable contaminants from the used refrigerant. The quality of recycled refrigerant can be measured on contaminated refrigerant samples according to standardized test methods (ARI 700). However, recycling is not common practice in the case of large food processing and cold storage units, where the preference is to recover and re-use the refrigerant.

4.4.6 Trends in consumption

The lifetime emissions of a refrigerant are dependent on the installation losses, leakage rate during operation, irregular events such as tube break and servicing losses including recovery loss and end-of-life loss during reinstallation/reconstruction. In some European countries, HCFC systems with more than 10 kg charge (including all application areas) showed an annual emission rate of 15% of the charge in the early 1990s (Naturvardsverket, 1996). This figure dropped to 9% in 1995 (UNEP 1998). Emissions from HFC systems are reported to be less than this, and this is probably due to more leak-proof designs. On a global scale, current CFC and HCFC annual emission rates are likely to be in the range of 10–12% of the charge (UNEP, 1998). A recent study (Clodic and Palandre, 2004) has provided estimates of emissions of CFCs, HCFCs, HFCs and ammonia from the combined sector of Food Processing, Cold Storage, and Industrial Refrigeration. Table 4.12 gives the percentage annual emissions of these refrigerants.

The consumption and banks of HFCs and other fluorocarbons have been estimated for the industrial refrigeration sector as a whole. Both a top-down (UNEP, 2003) and a bottom-up approach (Clodic and Palandre, 2004) are presented here (Table 4.13). The data for 2002 and the 2015 business-as-usual projections of Clodic and Palandre (2004) are used as a basis for the refrigeration subsectors in this report, so as to ensure consistency with other refrigeration and air conditioning subsectors (see Table 4.1). However, Table 4.13 clearly illustrates the differences between both approaches, which are clearly significant for CFCs.

Food processing and cold storage are assumed to account for 75% of the combined emissions and industrial refrigeration for the remaining 25% (UNEP, 2003).

The business-as-usual projections for 2015 show a significant increase in HFC consumption.

4.4.7 Comparison of HFC and non-HFC technologies

Energy efficiency and performance

As stated above R-404A and R-507A are the proven replacements for R-502 and this also includes the application in flooded evaporators used for food processing and cold storage systems. The cycle efficiencies are comparable to R-502 but significantly lower compared to those of ammonia (non-HFC technology) especially at high condensing temperatures (UNEP, 2003).

R-410A is another important HFC refrigerant in this sector. The energy efficiency of R-410A systems can be similar to ammonia for evaporation temperatures down to −40 °C, depending on compressor efficiency and condensing temperature. The efficiency below −40 °C until its normal boiling point of −51.6 °C is slightly higher for R-410A than that of ammonia and other refrigerants. The compressor efficiencies are also reported to be higher compared to HCFC-22, due to the high volumetric capacity (40% above that of HCFC-22) of R-410A (Meurer and König, 1999).

CO_2 technology is another non-HFC technology which is gaining momentum. CO_2 as a refrigerant is being used in food processing and cold storage units in cascade systems with ammonia in higher cascade. It has been reported that the volumetric refrigerating capacity of CO_2 is five times higher than HFC 410A and eight times higher than that of ammonia and other refrigerants. Therefore the size of most components in the system can be reduced (Roth and König, 2001). The efficiency of CO_2/ammonia cascade system in the temperature range of –40 °C to –55°C is comparable to a two-stage system with R-410A. CO_2 also shows a strong cost benefit in large systems (Axima, 2002).

Life cycle climate performance LCCP

Very limited data are available for TEWI/LCCP for this refrigeration sector. A recent publication (Hwang *et al*., 2004) reports a comprehensive experimental study of system performance and LCCP for an 11 kW refrigeration system operating with R-404A, R-410A and propane (HC-290) at evaporator temperatures of −20°C to 0°C. For a comparison on an equal first cost basis, the increased cost of safety features for HC-290 was used for a larger condenser for the HFC systems. The LCCP of the R-410A system was 4% lower and the LCCP of R-404A was 2% higher than that of the HC-290 system at an annual refrigerant emission rate of 2%. The LCCP values for R-410A and HC-290 were equal at an annual refrigerant emission rate of 5%.

4.5 Industrial refrigeration

4.5.1 Introduction

One characteristic of industrial refrigeration is the temperature range it embraces. While evaporating temperatures may be as high as 15°C, the range extends down to about –70°C.

Table 4.13. Estimated consumption and banks of halocarbons refrigerants for industrial refrigeration, including food processing and cold storage for 2002. (UNEP, 2003 and Clodic and Palandre, 2004).

		Consumption (kt yr^{-1})				Refrigerant Banks (kt)			
		CFCs	HCFCs	HFCs	NH_3	CFCs	HCFCs	HFCs	NH_3
2002	UNEP (2002)	12	28	5	-	109	165	9	-
2002	Clodic and Palandre (2004)	7	27	6	22	34	142	16	105
2015	Clodic and Palandre (2004)	4	24	18	27	21	126	85	123

Table 4.14. Major applications and refrigerants used in industrial refrigeration.

Application	Refrigerant	Other Refrigerants	CFC, HCFC Replacements
freeze drying	NH_3, HCFC-22	R-502	CO_2, R-410A
separation of gases	CFC-12, CFC-13, HCFC-22, R-503	-	PFC14, PFC-116, R-404A, R-507A, CO_2
solidification of substances	HCs, CFC-13, HCFC-22, CFC-12	-	HCs, CO_2, PFC-14, R-404A, R-507A
reaction process	Various		
humidity control of chemicals	CFC-12, CFC-13, HCFC-22, R-503		PFC-14, PFC-116, R-404A, R-507A, CO_2, NH_3, Air
industrial process air conditioning	NH_3, HCFC-22	R-502	NH_3, R-404A, HFC-134a, Water
refrigeration in manufacturing plants	Various		
refrigeration in construction	NH_3, R-502	HCFC-22	NH_3, CO_2, R-410A, R-404A, R-507A
ice rinks	NH_3, HCFC-22		NH_3, CO_2, R-404A, R-507A
wind tunnel	NH_3, R-502, HCFC-22, CFC-12	-	NH_3, R-404A, R-507A, HFC-134a
laboratories	Various		

At temperatures much lower than about –70°C the so-called ‘cryogenics’ technology comes into play. This produces and uses liquefied natural gas, liquid nitrogen, liquid oxygen and other low-temperature substances. Industrial refrigeration in this section covers refrigeration in chemical plants (separation of gases, solidification of substances, removal of reaction heat, humidity control of chemicals), process technology (industrial process air conditioning, refrigeration in manufacturing plants, refrigeration in construction), ice rinks and winter sports facilities, and laboratories where special conditions such as low temperatures, must be maintained. Some definitions of industrial refrigeration include food processing and cold storage; these are described in Section 4.4 of this chapter.

Industrial systems are generally custom-made and erected on site. A detailed description of industrial refrigeration and cold storage systems can be found in the ‘Industrial Refrigeration Handbook’ (Stoecker, 1998). Industrial refrigeration often consists of systems for special and/or large refrigerating purposes. The cooling/heating capacity of such units vary from 25 kW to 30 MW or even higher. These refrigeration systems are based on reciprocating, screw and centrifugal compressors, depending on the capacity and application.

Industrial refrigeration has mainly operated with two refrigerants: ammonia (60–70%) and HCFC-22 (15–20%). To a lesser extent CFC-502 (5–7%) has been used and other minor refrigerants complete the rest of industrial applications. Replacement refrigerants for CFCs and HCFCs, plus other non-fluorocarbon fluids are included in Table 4.14.

The refrigerants used are preferably single compound or azeotropic mixture refrigerants, as most of the systems concerned use flooded evaporators to achieve high thermodynamic efficiencies. Industrial refrigeration systems are normally located in industrial areas with very limited public access. For this reason ammonia is commonly used in many applications where the hazards of toxicity and flammability are clearly evident, well-defined, well understood and easily handled by competent personnel. Hydrocarbons may be used as an alternative to ammonia within sectors handling flammable fluids, such as chemical processing.

There are clear differences in how countries have developed the technology for industrial refrigeration since the starting of the CFC phase-out. In Europe, the use of HCFC-22 and HCFC-22 blends in new systems has been forbidden for all types of refrigerating equipment by European regulation 2037/00 (Official Journal, 2000) since 1 January 2001. The use of CFCs is also forbidden, that is no additional CFC shall be added for servicing. HFCs are occasionally used where ammonia or hydrocarbons are not acceptable, although they are not often preferred in Europe, as European users are expecting regulations limiting the use of GHGs in stationary refrigeration (see proposals in EU, 2004).

4.5.2 Technical options

Most of the industrial refrigerating systems use the vapour compression cycle. The refrigerant is often distributed with pumps to heat exchangers in the space or apparatus to be refrigerated. Indirect systems with heat transfer fluids are used to reduce the risk of direct contact with the refrigerant. Ammonia is the main refrigerant in this sector. HCFC-22, R-502 and CFC-12 are the historically used refrigerants from the group of CFCs and HCFCs. Beside the increasing share of ammonia for new systems, the current technical options to replace CFCs are HFCs, HCFC-22 and non-fluorocarbon technologies such as CO_2 and HCs.

4.5.3 Factors affecting emission reduction

The refrigerant charge in industrial systems varies from about 20 kg up to 10,000 kg or even more. Large ammonia refrigeration systems contain up to 60,000 kg of refrigerant. The high costs of the refrigerants, with the exception of ammonia and

CO_2, and the large refrigerant charge required for the proper operation of the plant have led to low emissions in industrial systems. In these systems annual average leakage rates of 7–10% are reported (UNEP, 2003); smallest leakage rates are observed in ammonia systems because of the pungent smell. Clodic and Palandre (2004) estimate somewhat higher annual leakage rates (17%) for the category of industrial refrigeration (which also includes food processing and cold storage). The abatement costs of refrigerant emissions from industrial refrigeration was determined to be in the range of 27–37 US$ (2002) per tonne CO_2 -eq (March, 1998). Cost data were calculated with a discount rate of 8%.

Design aspects

Industrial refrigeration systems are custom made and designs vary greatly from case to case. Due to the increasing requirements concerning safety and the quantity of refrigerant used in refrigeration systems, a design trend towards indirect systems has been observed over the past 10 years. Yet whenever possible, the majority of systems are still direct. Refrigerant piping fabrication and installation has changed from direct erection on site towards pre-assembled groups and welded connections (see Design aspects in Section 4.4.5 for additional information on design and installation practices to minimize refrigerant emissions).

Minimizing charge

There are limits on design optimization in terms of balancing low charge on the one hand against achieving high COPs or even stable conditions for liquid temperatures to be delivered to heat exchangers on the other. For example, flooded type evaporators represent the best technology available for a low temperature difference between the liquid to be cooled and distributed and the evaporating refrigerant, yet this requires large quantities of refrigerant. The increased use of plate heat exchangers, plate and shell heat exchangers, and printed circuit heat exchangers over the past 15 years has enabled the design of lower charge systems with flooded evaporators. Efforts to minimize the amount of refrigerant charge will continue with improvements in system technology.

Improved servicing practices

Trained service personnel are, according to safety standards (CEN-378, 2000/2001; ISO-5149, 1993), required for the maintenance and operation of industrial systems. Service and maintenance practices on industrial systems are updated periodically according to safety standards and service contracts, which are negotiated with the plant owner in the majority of the cases.

Recovery and recycling

Recovery of refrigerants from industrial plants is common in many countries and is sometimes also a requirement (CEN-378, 2000 and 2001). The recovery of small quantities of ammonia (less than 3 kg) through absorption in water is common practice. Larger quantities are recovered by special large recovery units and pressure vessels.

The recovery rate from industrial systems is high due to the high costs and quantity of the refrigerants, especially CFCs, HCFCs and HFCs. The recovery rate is estimated to be 92–97% of the refrigerant charge (UNEP, 2003). The recovered refrigerants are dried in the recovery systems on site and re-used.

Lifetime refrigerant emissions

As most industrial refrigeration systems are designed for specific manufacturing processes, information on lifetime emissions of refrigerants are not readily available. Even data on cooling capacities are often not official, as the production capacity of the manufactured product could be estimated from this data. However, the estimated annual leakage rates referred to in Section 4.5.3 should be noted.

4.5.4 HFC technologies

HFC refrigerants are options to replace CFC-114, CFC-12, CFC-13, R-502 and HCFC-22. The preferred HFCs are HFC-134a, HFC-23 and HFC-blends with insignificant temperature glide such as R-404A, R-410A and azeotropic blends like R-507A.

HFC-134a has completely replaced CFC-12 because of its comparable thermodynamic properties in various applications of industrial refrigeration. CFC-12 and HFC-134a are used in large systems for higher temperatures with evaporator temperatures from 15°C down to –10°C.

HFC-23 has replaced CFC-13 and to lesser extent CFC-503 for the same reasons as mentioned for CFC-12. The evaporator temperature range varies from –80°C to –55°C in the low-temperature applications of these refrigerants.

HFC-245fa, HFC-365mfc and HFC-236fa are possible replacements for CFC-114 in high-temperature heat pumps. No single fluid is ideal, especially for large industrial heat pumps, because the dew line of the fluids requires large superheat to avoid compression in the vapour region. The temperature range for condensing temperatures varies from 75°C to 100°C.

HFC-410A is not comparable to refrigerants HCFC-22 or CFC-12 in terms of thermodynamic properties because of its considerably higher vapour pressure. HFC-410A compressor efficiencies, the pressure drop in suction lines and the heat transfer efficiency will benefit from high system pressure. This HFC is used mainly in new industrial systems designed for the refrigerant, especially in terms of low condensing temperatures of 35°C to avoid pressures higher than 25 bar. In industrial refrigeration, the evaporator temperature range for HFC-410A varies from –60°C to –35°C. Due to the high volumetric capacity (40% above that of HCFC-22), compressor efficiency has been reported to be higher than with HCFC-22 (Meurer and König, 1999). R-410A has a COP similar to NH_3 and HCFC-22 and slightly higher than that of R-404A, R-507A. Further, at temperatures below –40°C and up to the to HFC-410A normal boiling point at –51.6°C, COPs are slightly higher for R-410A compared to other refrigerants (Roth *et al., 2002*).

R-404A and R-507A are the main refrigerants to replace R-502 in the temperature range from –50°C to –30°C and these have comparable cycle efficiencies (COPs) and slightly lower GWP values than R-502. For systems with R-404A and R-507A, the liquid should be subcooled to achieve optimum efficiencies and high cost-effectiveness . In chiller applications with screw compressors it may also be necessary to add significant superheat to the suction gas in order to avoid refrigerant condensation in the oil separator.

4.5.5 Non-HFC technologies

In large systems CFCs and recently introduced HFCs have a lower average share in industrial refrigeration than NH_3 and HCFC-22. For new industrial systems designers and plant owners will mainly need to decide between NH_3, HFCs and HCFC-22 (except in the EU where HCFC-22 is forbidden in new systems) (Stoecker, 1998). Non-HFC technologies described in the following subsection are sorted by refrigerant.

Ammonia

Ammonia is one of the leading refrigerants for industrial refrigeration, based on performance and safety, and is used in large quantities in locations physically separated from general public access. The current market share in several European countries, especially in Northern Europe, is estimated to be up to 80% (UNEP, 1998). In the USA, ammonia has approximately 90% market share in systems of 100 kW cooling capacity and above that use custom-engineered processes (IIR, 1996).

New ammonia systems have an improved design, use low-temperature materials and standardized welding procedures, and the systems operation and maintenance are under continuous monitoring. A human error or direct physical damage is often the reason for failure (Lindborg, 2003).

Charge reduction has been achieved through dry or direct expansion in plate type heat exchangers and shell and tube evaporators. With soluble oils, it has been possible to reduce charge by 10%. New developments showed charges of 28g ammonia per kW cooling capacity for low overall capacity down to 100 kW (Behnert and König, 2003). With these low charges, new opportunities for applications not previously considered for ammonia have been realized, such as water chillers for air conditioning (Stoecker, 1998). This new ammonia technology with high COP was regarded as being fully practical, but strong market penetration has not been achieved due to price competition with HFC-based units (UNEP, 2003).

HCFC-22

The use of HCFC-22 is declining in industrial refrigeration in Europe, as the use of HCFC-22 in new systems is forbidden by European regulations (Official Journal, 2000).

In developing countries, HCFC-22 is still an important replacement refrigerant for CFCs in new systems, as from a technical point of view HCFC-22 could replace CFC-12 and CFC-502 in new systems. Another important consideration in developing countries is that under the Montreal Protocol the production of HCFC-22 is allowed until 2040, or the full lifetimes of equipment installed in the next 15 years or so.

Hydrocarbons (HCs)

HCs can fit into any temperature range for evaporating temperatures down to –170°C. Historically, their use as working fluids has been restricted to large refrigeration plants within the oil and gas industry. A certain registered increase in hydrocarbon consumption has mainly appeared in these sectors (Stoecker, 1998).

Commercialized products used in industrial refrigeration equipment include HC-290 and HC-1270. System performance with regard to system efficiency is comparable to and, in some cases even superior to, that of the halocarbons. Hydrocarbons are soluble with mineral oils and compatible with materials such as metals and elastomers that are traditionally used in refrigeration equipment. The use of hydrocarbons in screw compressors may be problematic due to the strong dilution of mineral oil. Other less soluble lubricants such as PAG or PAO may be required. As long as safety aspects are taken into consideration, standard refrigeration practices used for HCFCs and CFCs can be used for hydrocarbon fluids without major system detriment.

Given the flammability concerns, design considerations as detailed in the relevant safety standards should be adhered to. Additional safety measures are required for repairing and servicing. Several national and European standards permit the use of HCs in industrial applications and lay down specific safety requirements. Industry guidelines for the safe use of hydrocarbon refrigerants are available (ACRIB, 2001).

Carbon dioxide (CO_2)

As well as being non-ODP and having a GWP of 1, carbon dioxide (CO_2) offers a number of other advantages:

- Excellent thermophysical properties, leading to high heat transfer;
- Efficient compression and compact system design due to high volumetric capacity;
- Non-flammable and low toxicity;
- Low system costs at evaporation temperatures below 45°C (depending on system design);
- Widely available at low cost.

CO_2 systems can be used for industrial refrigeration applications with evaporation temperatures down to –52°C and condensing temperatures up to 5°C. CO_2 is also increasingly being used in the low stage of cascade systems for industrial refrigeration. CO_2 is also commonly used as a secondary refrigerant. The design requires the same pressure of 25 bar for the secondary refrigerant systems and for the CO_2 used as the refrigerant, except for ice rinks and some other limited systems which are designed for 40 bar. Defrosting was an open issue, but the most recent developments show that several different techniques such as electrical heating, hot gas defrosting, high-pressure liquid evaporation and the distribution of hot gas have been realized in plants (Siegel and Metger, 2003).

A comparative study for low temperatures has been carried out using a typical system design with cooling capacities of 600kW at −54°C for R-410A, R-507 and ammonia used as a single fluid in two-stage systems and for NH_3/CO_2 and HFC-134a/R-410A as refrigerants in high/low stage cascade systems. The volumetric refrigerating capacity of CO_2 is five times higher than HFC-410A and eight times higher than for ammonia and other refrigerants. Therefore the size of most components in the system can be reduced. The study found the lowest cost for NH_3/CO_2 (Roth *et al., 2002*). If CO_2 is used as the refrigerant, the cost break-even point for industrial refrigeration compared to NH_3 and R-410A is approximately at an evaporating temperature of –40°C to −45°C. Below this temperature, lower costs for CO_2/NH_3 cascade systems have been achieved. It is expected that costs for screw or reciprocating units, including compressors and oil separation circuit, will be further reduced (Roth *et al., 2002*). The efficiency of CO_2 systems in this low temperature range is similar to other refrigerants such as R-410A or ammonia.

CO_2 shows strong cost benefits if the system size is increased, especially in cases where evaporators or heat exchangers are distributed and long piping systems are required. In industrial refrigeration applications, cost benefits have been achieved with total pipe runs of more than 2500 m (Siegel and Metzger, 2003).

In food processing, a trend can be observed towards CO_2 as a refrigerant at temperatures lower than –45°C and as an HTF for cooling temperatures lower than −5°C (Pirard, 2002).

Some examples are given to illustrate the use of CO_2 as refrigerant in low-temperature applications:

- In the USA, the first large CO_2 system was being erected in 2003 with cooling capacities of 6 MW (Stellar, 2003);
- In Japan a standard low-temperature cascade system has been developed with NH_3/CO_2 as refrigerants. The systems are designed for evaporating temperatures of –40 to –55°C with cooling capacities of 80−4450 kW;
- In Europe more than 30 large systems with CO_2 as the heat transfer fluid and refrigerant have been installed since 1998 and are operating with total cooling capacities of more than 25 MW (Pearson, 2004a,b);
- At least two large systems in Europe have been retrofitted from HCFC-22 (1.5 MW at −45 to −55°C) and from CFC-13B1 (2.4 MW at −35°C) to NH_3/CO_2 cascade systems (Gebhardt, 2001; König, 2002).

4.5.6 Trends in consumption

The trends in the consumption of refrigerants for industrial refrigeration as well as the food processing and cold storage subsector are discussed in Section 4.4.6.

4.5.7 Comparison of HFC and non-HFC technologies

4.5.7.1 Energy efficiency and performance

On a worldwide basis, only two refrigerants have significant market share in industrial refrigeration: ammonia and HCFC-22. Stoecker (1998) provides a comparison of both refrigerants. Compared to ammonia and HCFC-22, the market share of HFCs and non-HFC technologies is small. Nevertheless, one point of comparison is the cost of the refrigerant to be used in the system, and the lowest costs are found for ammonia (Stoecker, 1998).

The energy efficiency comparisons for HFCs 404A, 507A, and 410A with ammonia and HCFC-22 are described in Section 4.5.4. HFC410A has an energy efficiency similar to ammonia and HCFC-22, and slightly higher than R-404A and R-507A (Roth *et al*., 2002).

CO_2 technology is a non-HFC technology which is gaining momentum. The energy efficiency of CO_2 systems in the temperature range of –40ºC to –45ºC is similar to HCFC-22 and HFC refrigerants such as HFC-410A. CO_2 also shows strong cost benefit if the system size is large (Siegel and Metzger, 2003).

4.5.7.2 TEWI/LCCP/LCA

For various reasons, only limited TEWI/LCCP/LCA data are available for industrial refrigeration systems. Such systems are normally custom-designed for special requirements and are erected on site. The design differs not only in terms of cooling capacities and temperatures, but also in terms of temperature control requirements (air blast cooling systems), size of piping, distance to consumers and charge of refrigerant. There are therefore only a few references which compare TEWI and costs for the same application (Pearson , 2004a; Roth *et al*., 2002). Roth *et al*. (2002) give a comparative example for a manufacturing plant with a cooling capacity of 600 kW at −54°C (see Figures 4.1 and 4.2). In this investigation the combination of CO_2 and ammonia was more competitive than other solutions.

In addition to the above references, examples of LCCP calculations for supermarket refrigeration systems provide general guidance for selecting systems and refrigerants with a lower LCCP (see Section 4.3). Lower LCCP results from systems with low energy consumption, and in the case of fluorocarbon refrigerants, low refrigerant charge size and low refrigerant emissions. LCCP calculations should be used to optimize the choice of refrigerant and system design for the lowest environmental impact.

4.6 Transport refrigeration

4.6.1 Introduction

The transport refrigeration subsector consists of refrigeration systems for transporting chilled or frozen goods. Typically the task of a transport refrigeration system is to keep the temperature constant during transport. The technical requirements for transport refrigeration units are more severe than for many other applications of refrigeration. The equipment has to operate in a wide range of ambient temperatures and under extremely variable weather conditions (sun radiation, rain, etc.); it also has to be able to carry any one of a wide range of cargoes with

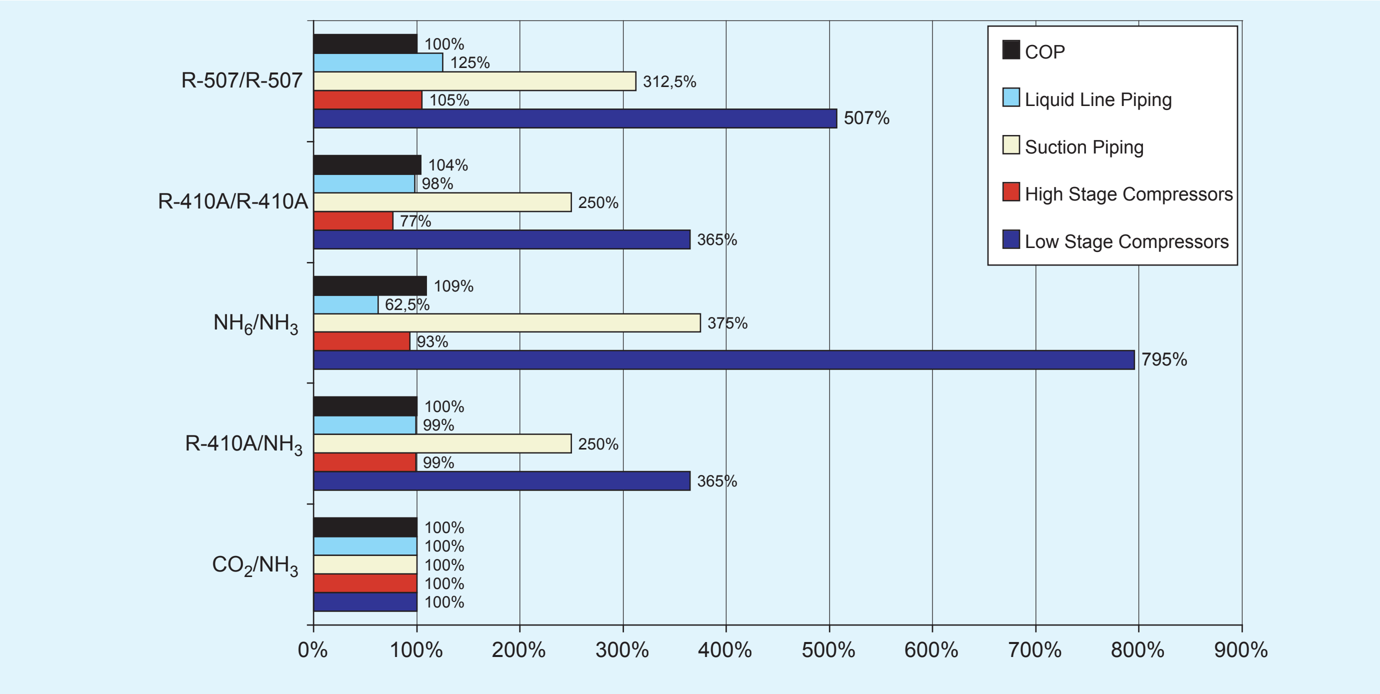

Figure 4.1. COP and size comparison of different components for different refrigerant combinations (Q_0 = 600 kW, t_C = 35°C; t_0 = −54°C; CO_2/NH_3-cascade system is equal to 100 %) (Roth and König, 2002).

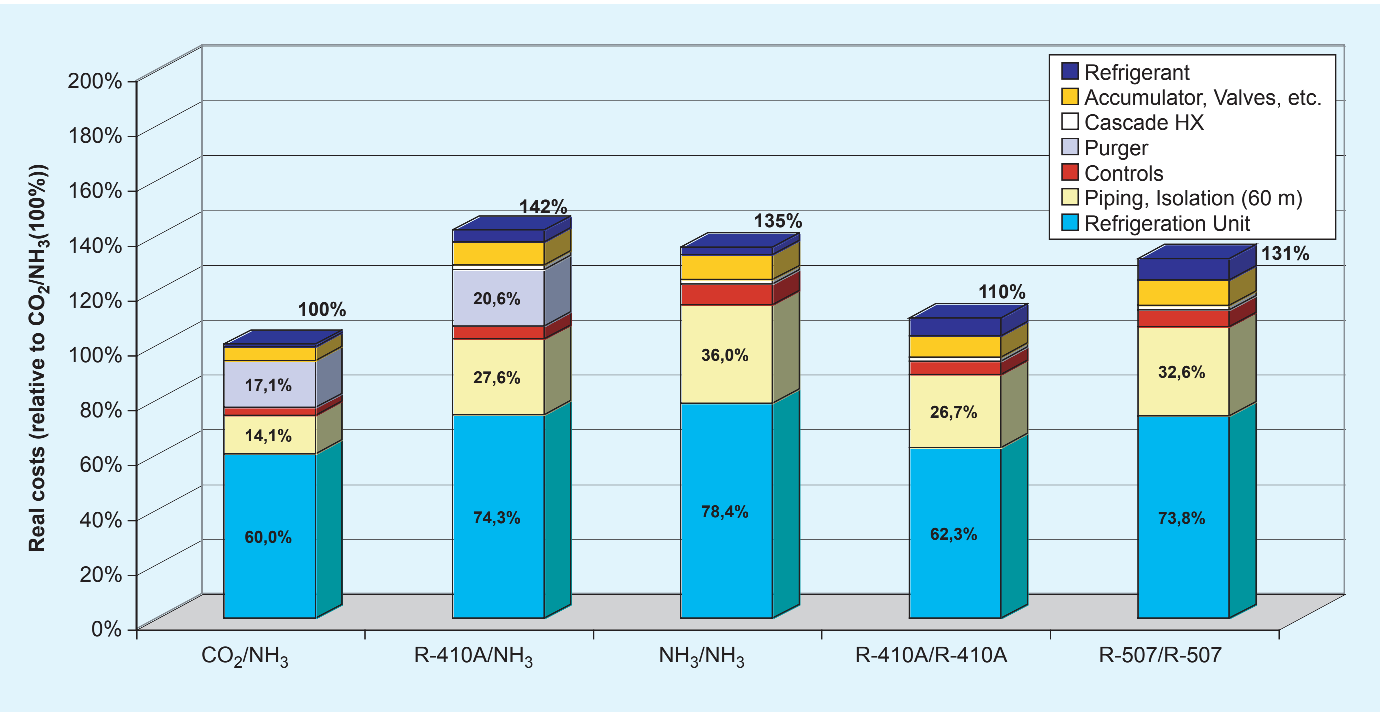

Figure 4.2. Cost comparison for different refrigerant combinations (Q_0 = 600 kW, t_C = 35°C; t_0 = −54°C; CO_2/NH_3-cascade system is equal to 100 % (Roth and König, 2002).

differing temperature requirements, and it must be robust and reliable in the often severe transport environment (IIR, 2003). Typical modes of transport are road, rail, air and sea. In addition, systems which are independent of a moving carrier are also used; such systems are generally called 'intermodal' and can be found as containers (combined sea-land transport) as well as swap bodies (combined road and rail transport). This section covers also the use of refrigeration in fishing vessels where the refrigeration systems are used for both food processing and storage.

The technology used in transport refrigeration is mainly the mechanically- or electrically-driven vapour compression cycle using refrigerants such as CFC, HCFC, HFC, ammonia or carbon dioxide. Due to the complete and worldwide phase-out of CFC consumption by the end of 2009, CFCs are not addressed in this chapter. In addition, a number of refrigeration systems are based on using substances in discontinuous uses. This type of equipment can be found as open uses with solid or liquid CO_2, ice, or liquid nitrogen and in these cases the refrigerant is being completely emitted and lost after removing the heat (Viegas, 2003). Closed systems such as eutectic plates (Cube *et al.*, 1997) or flow-ice, reuse the same substance (Paul, 1999). Such systems used to be very commonplace in transport refrigeration, and are still used on a significant scale. Some propose that their use should be increased in the future.

All transport refrigeration systems need to be compact and lightweight, as well as highly robust and sturdy so that they can withstand movements and accelerations during transportation. Despite these efforts, leaks within the refrigeration system occur due to vibrations, sudden shocks and so forth. The likelihood of leaks or ruptures is also greater than with stationary systems, due to a higher risk of collisions with other objects. Ensuring safe operation with all working fluids is essential, particularly in the case of ships where there are no options to evacuate a larger area (SCANVAC, 2001). The safety is either inherent in the fluids or is ensured through a number of technical measures (Stera, 1999).

4.6.2 Container transport

Refrigerated containers allow uninterrupted storage during transport on different types of mobile platforms, for example railways, road trucks and ships. The two main types of refrigerated containers are porthole containers and integral containers. Porthole containers are the older of the two concepts and are insulated containers with two front apertures and no built-in refrigeration systems. Some predict that by 2006, transport will have been completely converted to integral containers (Hochhaus, 2003; Wild, 2003).

Integral refrigerated containers are systems which have their own small refrigeration unit of about 5 kW refrigeration capacity on board. There were more than 550,000 of these in 2000, representing the transport capacity of 715,000 20-foot containers, and there numbers are set to strongly increase (UNEP, 2003; Sinclair, 1999; Stera, 1999). The electrical power needed to drive the system is supplied from an external power supply via an electrical connection. These systems typically use HFC-134a, R-404A and HCFC-22, and in some cases R-407C (Wild, 2003). Newer systems generally have a more leak-resistant design (Crombie, 1999; Stera, 1999; Yoshida *et al.,* 2003; Wild, 2003). In 1998, when older design systems were prevalent, an average annual leakage rate of 20% of the charge of about 5 kg was assumed for a lifetime of 15 years (Kauffeld and Christensen, 1998).

4.6.3 Sea transport and fishing vessels

Virtually all of the 35,000 plus merchant ships worldwide larger than 500 gross tonnes (Hochhaus, 1998) have some on-board refrigeration system. The majority of systems use HCFC-22. These refrigeration systems and options for emission abatement are referred to in Sections 4.2 and 4.3 of this report. In terms of technology and performance, chillers for air conditioning or, in case of naval vessels for electronics and weapon system cooling, are similar to stationary systems (see section 5.1 on air conditioning). The following remarks and information relate to ship-bound refrigeration systems essential to the main purpose of non-naval vessels, namely the transportation of perishable products, the chilling of fish and the like.

Refrigerated transport vessels, also called reefers, provide transportation for perishable foodstuff at temperatures between –30°C and 16°C (Cube *et al*., 1997). It is estimated that there are around 1300 to 1400 reefer vessels in operation (Hochhaus, 2002; Hochhaus, 1998), a number which has been constant for quite some time and is expected to decrease. In 2001, it was reported that more than 95% of the refrigeration installations on these vessels use HCFC-22 as a refrigerant (SCANVAC, 2001), although various HFCs such as HFC-134a, R-404A, R-507 and R-407C as well as ammonia are being used. About two-thirds of the systems are direct systems with up to 5 tonnes of refrigerant per system and the remaining are indirect systems with a charge below 1 tonne of refrigerant (UNEP, 2003). Estimates of current annual leakage rates based on known refrigerant consumption are 15−20% of the system charge (SCANVAC, 2001).

Worldwide there about 1.3 million decked and about 1.0 million undecked, powered fishing vessels. In 2001, more than 21,500 fishing vessels over 100 gross tonnes were recorded (FAO, 2002), with a slightly decreasing trend. Vessels of that size are assumed to operate internationally and to be equipped with significant refrigeration equipment. Within a wide range, the average larger fishing vessel has a refrigerant charge in the order of 2000 kg with 15−20% annual leakage rate. In 2001 more than 95% of such vessels in Europe used HCFC-22 as the refrigerant (SCANVAC, 2001). It is assumed that 15% of the fleet have full size refrigeration systems, while the remaining fleet is assumed to be equipped with small refrigeration systems that have a filling mass of approximately 100 kg.

Specialized tankers are used to transport liquefied gases, in particular liquefied petrol gas (LPG) and liquefied natural gas (LNG). Medium and large LNG tankers transport LNG at normal pressure. The refrigeration effect needed for this type of transport is provided by evaporating the LNG, which is recondensed using specialized refrigeration units. Since the number of such ships is limited (about 150 ships of above 50,000 tonnes were registered in 1996) (Cube *et al*., 1997) and the refrigeration equipment typically uses the transported, low GWP hydrocarbon gases as the refrigerant, refrigeration use in gas tankers is not further considered in this report.

4.6.4 Road transport

Road transport refrigeration units, with the exception of refrigeration containers, are van, truck or trailer mounted systems. Some trailers are equipped to be mounted or have their main bodies mounted on railroad systems; these are so-called swap-bodies. In a number of uses those systems are of the discontinuous type, using eutectic plates in closed systems (Cube *et al*., 1997) or liquid nitrogen, liquid carbon dioxide or solid carbon dioxide in open systems (UNEP, 2003). These systems are frequently used in local frozen food distribution, for example, delivery directly to the customer (Cube *et al*., 1997). Liquid nitrogen for cooling purposes is used by more than 1000 vehicles in the UK. Liquid carbon dioxide is reported to be used in 50 trucks in Sweden (UNEP, 2003). In general, the necessity for storage and filling logistics, the hazardous handling of very cold liquids and solids and the energetically unfavourable low-temperature storage reduce the widespread application of these historically frequently used technologies.

The predominant technology in road transport, covering virtually all of the remaining refrigerated road transport equipment, is the mechanical vapour compression cycle. Trailers usually have unitary equipment that consists of a diesel engine, compressor, condenser, engine radiator and evaporator with fans as well as refrigerant and controls. These systems are also used for swap bodies. Larger trucks often have similar equipment as trailers. However, as the truck size decreases an increasing proportion of systems have the compressor being driven by the drive engine (ASHRAE, 2002). Alternatively, some truck systems use a generator coupled with the truck engine to generate electricity, which is then used to drive the compressor (Cube *et al*., 1997).

In 1999, it was estimated that in North America alone 300,000 refrigerated trailers were in use (Lang, 1999). For the 15 countries of the European Union in 2000, 120,000 small trucks, vans and eutectic systems with 2 kg refrigerant charge were estimated to be in use, with 70,000 mid-size trucks of 5 kg refrigerant filling and 90,000 trailers with 7.5 kg refrigerant filling (Valentin, 1999). The worldwide numbers in 2002 were estimated to total 1,200,000 units, with 30% trailer units, 40% independent truck units and 30% smaller units. The annual amount of refrigerant needed for service is reported to be 20–25% of the refrigerant charge (UNEP, 2003). The refrigerant typically chosen is HFC-134a for applications where only cooling is needed, and predominantly R-404A and R-410A for freezing applications and general-purpose refrigeration units (UNEP, 2003).

4.6.5 Railway transport

Refrigerated railway transport is used in North America, Europe, Asia and Australia. The transport is carried out by using either refrigerated railcars, or refrigerated containers (combined sea-land transport; see Section 4.6.2) or swap bodies (combined road-land transport; see Section 4.6.4). This section concentrates on transport in refrigerated railcars.

Different technologies have been used in the past: Solid CO_2 as well as ice have been used in discontinuous emissive systems to date (CTI, 2004). Mechanically-driven refrigeration systems have also been used and are now the prime choice because of the typically long duration of trips, which makes refilling of the emitted refrigerant in discontinuous emissive systems a challenge for both logistical and cost reasons.

Mechanically driven systems are almost completely equipped with diesel engines to supply the necessary energy to the refrigeration unit. The existing fleets of railcars in Asia still seem to mostly operate on one-stage (cooling) and two-stage (freezing /combined use) CFC-12 systems (UNEP, 2003). The European railcars have been converted to HFC-134a (Cube *et al*., 1997), and this has been facilitated by European regulations phasing out the use of CFCs (EC No 2037/2000 (Official Journal, 2000)). In North America, existing older systems have been converted to HFC-134a, while newer systems utilize HFC-134a and R-404A (DuPont, 2004).

The lifetime of newer rail refrigeration systems, which are often easily replaceable units originally developed for road transport and only adapted for rail use, is believed to be 8 to 10 years with a running time of 1000 to 1200 hours per annum (refrigeratedtrans.com, 2004). Older units specifically designed for rail use have a lifetime of typically 40 years and a refrigerant filling of approximately 15 kg (UNEP, 2003). The annual leakage rate may be assumed to be at least similar to the leakage rate experienced in road transport, that is 20–25% of the refrigerant charge (UNEP, 2003).

4.6.6 Air transport

In order to provide constant low temperature during the flight, containers to be loaded upon aircraft are provided with refrigeration systems. There are some battery powered mechanical refrigeration systems (Stera, 1999), but the total number of these is believed to be small. Other, more commonly used systems are discontinuous with solid carbon dioxide (Sinclair, 1999; ASHRAE, 2002), or ice (ASHRAE, 2002). As the amount of ODS replacement during use is apparently very small, air transport will not be detailed further in this report.

4.6.7 Abatement options

4.6.7.1 General

Based on the study of Clodic and Palandre (2004), the total amount of refrigerant contained in transport refrigeration systems is estimated to be 16,000 tonnes; 6000 tonnes of this are emitted annually. It should be noted that the widespread use of R-404A as a non-ODS alternative with a relatively high GWP of 3800 kg CO_2 kg^{-1} leads to very high CO_2-equivalent emissions. Using alternatives in systems with a more moderate GWP than R-404A, such as the HFC mixture R-410A, would cut the CO_2-equivalent emissions substantially.

Current system requirements lead to a refrigerant selection which is largely limited to HFC-134a and refrigerant mixtures with a relatively high global-warming impact such as R-404A. Since the emission rates in operation are significant, improvements in energy consumption, alternative substances and not-in-kind technologies are the main options for emission abatement. R-404A is the main refrigerant in current use (IIR, 2002) and is popular because of its flexibility (medium- and low-temperature applications) and safety. Only a limited number of TEWI calculations are available in the literature; the only investigation comparing different technologies such as CFC-12, HFC-134a, R-404A, HC-600a/HC-290, ammonia and CO_2, states that R-404A systems are at least sustainable from the different options investigated for reefer ships (Meffert and Ferreira, 2003).

4.6.7.2 Containment

As there are already considerable incentives to optimize design and to minimize leakage, further containment in most uses would require a new approach not yet seen. One example might be to use fully hermetic systems for road transport (Chopko and Stumpf, 2003a, b), although the effect of this on energy consumption has yet to be determined. The development of hermetic scroll compressors for container systems with acceptable energy efficiency for both cooling and freezing applications (Yoshida *et al.,* 2003; DeVore, 1998) allows their widespread use, and leads to less service requirements and therefore less related refrigerant losses. In addition, these compressors are hermetic, which further decreases leaks (Wild, 2003). This technology has already been introduced and is penetrating the market as existing equipment is gradually replaced.

Recovery and recycling is a statutory requirement in many countries and is probably adhered to since the equipment contains a considerable, but still easy-to-handle, amount of refrigerant and due to its mobility it can easily be transported to a recovery facility (except seagoing). On the other hand due to the large emission rates in operation, the improvements through recovery and recycling, which encompass only the refrigerant losses during service and disposal, are likely to be limited.

An alternative approach to improving systems to reduce leaks might be to improve operating conditions to reduce wear, likeliness of ruptures and refrigerant losses during service. The potential of such measures compared to system-related improvements has yet to be assessed, but might be considerable.

4.6.7.3 Improvement in energy efficiency

Most refrigeration systems operate under partial load conditions for a large proportion of their useful life (Meffert and Ferreira, 1999). Different methods for partial load control have been investigated for both electrically driven compressors and open compressors (e.g. Crombie, 1999). Potential energy savings for electrical systems using frequency converters are said to reach up to 25.8% per voyage (Han and Gan, 2003). Other sources compare a range of control possibilities (Meffert and Ferreira, 1999 and 2003). These sources concluded that energy efficiency gains of more than 70% can be achieved under part-load conditions.

4.6.7.4 Discontinuous processes

The use of ice as well as solid CO_2 are both established alternatives to vapour compression systems. Besides the logistical necessities of such systems, there are also temperature limitations for the use of ice as well as handling and energy issues when using solid CO_2 (as heat absorption is energetically unfavourable at –78.4°C). These issues are even more valid for the use of liquid nitrogen, producing an unnecessarily low temperature of –195.8°C, or liquid air with –194.3°C. Nevertheless, refrigerated systems using ice and solid CO_2 systems remain abatement option for HFC in suitable cases.

The commercialization of a fully self-powered liquid CO_2 system with a moderate evaporation temperature of –51°C for the delivery of frozen product to customers was reported by Viegas (2003), and this addressed handling as well as energy efficiency issues. The system, which needs a service infrastructure, has been commercialized in Sweden (Viegas, 2003) and the UK (UNEP, 2003) and is therefore available as an abatement option, especially for local and short-haul transport.

The use of a pumpable suspension of ice crystals in water (‘binary ice’, ‘flow ice’), has been developed for certain transport uses. The suspension is pumped into the hollow walls, floors, ceilings or trays of a containment to be refrigerated. While equipment for service trolleys for passenger trains is already commercially available, the same principle is being suggested for containers (Paul, 1999). Although the remaining technical issues seem to be standard engineering tasks, the technology is not yet commercially available for cooling of full containers, trucks or vans.

4.6.7.5 Sorption processes

Sorption processes are well known, heat-driven processes using water, methanol or ammonia as a refrigerant, and solids such as activated coal, zeolite or silica gel (adsorption) as well as liquids such as lithium bromide (LiBr) and water (absorption) as sorbents in a closed circuit. The heat to drive such processes can come from a variety of sources; in the case of transport refrigeration, the waste heat from the transporter’s engine could be used. Such a use has been proposed for several years, especially for ship-bound systems (Cube *et al*., 1997).

LiBr-water systems, are frequently used in stationary applications and for the capacity range of 200 kW–600 kW, these have been reported to operate successfully and produce chilled water in certain specialized ships (Han and Zheng, 1999). Below zero refrigeration is not feasible with LiBr-water systems. As such systems have already been successfully employed on ships, their utilization might be increased at a relatively short notice.

The applicability to modes of transportation other than ships might be limited because of downscaling problems as well as design restrictions on those systems.

For truck-mounted refrigeration systems, the use of waste heat from the truck engine has been suggested to drive a water-ammonia sorption cycle (Garrabrant, 2003). For medium and small fishing vessels, adsorption ice-makers with carbon-methanol are being proposed, which utilize the exhaust heat of the ship's engine as an energy source (Wang *et al*., 2003).

4.6.7.6 Hydrocarbons

Hydrocarbon cooling systems for the recondensation of transported hydrocarbons have successfully been installed in gas tankers. International activities are underway to develop hydrocarbon systems for reefer ships (Jakobsen, 1998). In road transport refrigeration, commercially available systems have been developed in Australia, Germany and other European countries using HC-290 (propane). The systems require a leak detector in the trailer and special driver training to fulfil safety-related legal requirements (UNEP, 2003; Frigoblock, 2004).

Technically this solution could be adopted worldwide in certain road and railroad systems, especially in compact systems. Nevertheless, either certain existing regulations or present system use patterns would have to be adapted. The flammability of hydrocarbons will require additional safety measures, thus increasing the costs of the system, and in the beginning at least probably insurance rates as well. Containers might also require changes in the transporting ships.

4.6.7.7 Ammonia

Ammonia as refrigerant is being increasingly used in marine refrigeration equipment. Applications include its use in reefers (Stera, 1999), as a proposed refrigerant for sorption ice machines (Garrabrant, 2003), and the use in fishing vessels both as a single refrigerant (UNEP, 2003; Berends, 2002) and in combination with CO_2 (Nielsen and Lund, 2003). The applicability has been sufficiently proven. Ammonia as a refrigerant requires certain design considerations as well as the presence of additional safety equipment on board (SCANVAC, 2001).

4.6.7.8 Carbon Dioxide

Carbon dioxide as a refrigerant in mechanically-driven vapour compression systems, might be used as a subcritical refrigerant (critical point at 31°C) with a condensing temperature well below the critical point in cascade systems or in applications where low-temperature cooling options means are available. Alternatively, it can be used as a near-critical or, more likely, a super-critical working fluid. If the condensing temperature of CO_2 is below 15°C (border of subcritical region), this refrigerant typically offers, but not always, significant advantages in terms of efficiency and costs in comparison to other refrigerants. This advantage can only be utilized in cascade systems with other refrigerants or where low-temperature heat sinks are available. Near- or super-critical uses require a much higher pressure resistance of the equipment than is currently usual for other refrigerants, and such uses are often energetically less favourable than other refrigerants in the same temperature range.

For low-temperature uses, combinations of ammonia and CO_2 have been developed and built into ships. A comparison shows that the efficiency for a –40°C evaporation and 25°C condensing temperature is 17% higher than for a 2-stage HCFC-22 system (25% improvement at –50°C/25°C) (Nielson and Lund, 2003). The advantage of using CO_2 in such applications is that the necessary components (in particular the compressor) are commercially available or require only minor modifications, while consuming less space than other solutions.

CO_2 has also been proposed for container systems, where it would typically be used in a super-critical manner. A prototype system has yet to be reported as until recently no suitable compressor was available. A prototype CO_2 system for trucks has been developed, laboratory tested and optimized (Sonnekalb, 2000). The calculated TEWI shows a 20% decrease compared to a R-404A system.

4.6.7.9 Air

The air cycle for transport refrigeration purposes has been investigated for a number of years (e.g. Halm, 2000). A prototype system has been developed and tested, but has never been commercialized. Presently air cycle equipment for transport refrigeration does not seem to represent a suitable short- or medium-term abatement option due to the lack of suitable and reliable components.

4.6.8 Comparison of alternatives

Emissions of halocarbons in the transport refrigeration sector are related to four subsectors: Sea transport and fishing, road transport, rail transport and intermodal transport, that is containers and swap bodies. An overview can be found in Table 4.15.

There are a number of possibilities to improve those transport refrigeration systems built today to achieve a lowering of direct or energy-consumption related emissions without changing the working fluid or technology. A number of measures have been proposed and these have in part already been implemented to improve the energy efficiency, for example, the use of efficient compressors, frequency control for part load conditions, water-cooled condensers for containers on board ships, regular preventive maintenance and so forth. Measures to control direct emissions have mainly been proposed for mass-produced systems (e.g. container units) in terms of design improvements.

An alternative to improving the currently predominant halocarbon technologies is the replacement of those refrigerants by fluids or technologies with a lower GWP. Technically there are or will be low GWP replacement options available for all transport refrigeration uses where CFCs, HCFCs or HFCs are currently used. However in several cases these might increase the costs of the refrigeration system.

In case of reefer ships and fishing vessels, the most promising and already implemented non-halocarbon abatement tech-

Table 4.15. Subsectors of transport refrigeration, characteristics and alternatives.

Subsector		Sea Transport & Fishing	Road Transport	Rail Transport	Intermodal Transport
Cooling capacity	From To	5 kW 1400 kW	2 kW 30 kW	10 kW 30 kW	Approx. 5 kW
Refrigerant charge	From To	1 kg Several tonnes	1 kg 20 kg	10 kg 20 kg	Approx. 5 kg
Approximate percentage of sector refrigerant bank in subsector		52% of 15,900 tonnes	27% of 15,900 tonnes	5% of 15,900 tonnes	16% of 15,900 tonnes
Approximate percentage of sector refrigerant emissions in subsector		46% of 6000 tonnes	30% of 6000 tonnes	6% of 6000 tonnes	18% of 6000 tonnes
Predominant technology		HCFC-22	HFC-134a, HFC-404A, HFC-410A	HFC-134a, HFC-404A, HFC-410A	HFC-404A
Other commercialized technologies		Various HFCs, ammonia, ammonia, CO_2 /ammonia for low temperatures; hydrocarbon systems for gas tankers; sorption systems for part of the cooling load	Hydrocarbon, liquid CO_2; with unknown systems for liquefaction/freezing: liquid CO_2, ice slurry; with on-board HCFC/HFC refrigeration systems: Eutectic plates	Solid CO_2 (with unknown systems for freezing)	HFC-134a, HCFC-22
Low GWP technologies with fair or better than fair potential for replacement of HCFC/HFC in the markets		Ammonia, CO_2 /ammonia for low temperatures	Hydrocarbon, CO_2 compression systems; for short haul combination of stationary hydrocarbon or ammonia with liquid CO_2, ice slurry or eutectic plates	Hydrocarbon, CO_2 compression systems; for specific transports (certain fruits, ...) combination of stationary hydrocarbon or ammonia with liquid CO_2, ice slurry or eutectic plates	CO_2 compression system
Status of alternatives		Fully developed. Some cost issues related to additional safety for ammonia plants on ships. Hydrocarbon practical mainly for ships which are built according to explosion-proof standards (gas carriers, ...)	Hydrocarbon mini-series successfully field tested, lack of demand/add. requirements on utilization (driver training, parking, ...). Liquid CO_2 systems commercialized. CO_2 compression tested in prototypes, but open compressor needed for most systems in combination with leaks remains an issue	Solid CO_2 standard use, but not very energy efficient, difficult handling, high infrastructure requirements, therefore presently being phased out. Increasingly use of systems designed for trailer use with optimization for rail requirements (shock resistance, ...)	Under development – prototype testing; might be available in the near future if demanded

nology is equipment with ammonia or ammonia/CO_2 systems. These systems are likely to operate at least as energy efficiently as existing systems. One source (SCANVAC, 2001) estimates the additional costs for a ship-bound ammonia system to be 20–30% higher if retrofitted into an existing vessel and potentially lower if included in the ships planning from the start. Another source (Nielsen and Lund, 2003) assumes that small industrial ammonia/CO_2 systems might be more expensive than conventional systems, but large systems might have a more or less equivalent price for the same capacity.

In the case of container systems, CO_2 in a vapour compression cycle could develop into a promising alternative. The costs for the refrigeration system might be higher than for current conventional systems. The energy consumption will probably be higher if the containers are only air-cooled but if additional water-cooling is installed, as has already implemented on some vessels, the systems could be energetically as good as or even better than existing equipment.

Options using CO_2 and hydrocarbons exist for road transport. The hydrocarbon technology is technically implementable within a short time frame. For larger systems, CO_2 systems or hydrocarbon refrigerants are potential options, depending on the safety issues. The same alternatives could be used for new railway systems. Certain types of refrigerated road transport, such as short-range distribution trucks, might use discontinuous systems with evaporating CO_2 or nitrogen as alternative.

As transport refrigeration systems have very significant emissions and a limited runtime, which is typically far below

100%, direct emissions play a very important role in the calculation of the TEWI. The replacement options currently being considered by manufacturers do not significantly increase transport weight or volume. The data is sufficient to state that in several applications, a substantial reduction in TEWI could be achieved by introducing a low GWP technology.

Perfluorohexane	C_6F_{14}	3,200	5,000	7,400	10,700
Ozone-depleting substances†	e.g., CFCs and HCFCS				

§ Derived from the Bern carbon cycle model.

* The GWP for methane includes indirect effects of tropospheric ozone production and stratospheric water vapour production, as in IPCC (1994). The updated adjustment time for methane is discussed in Section B.2.

† The Global Warming Potentials for ozone-depleting substances (including all CFCs, HCFCs and halons, whose direct GWPs have been given in previous reports) are a sum of a direct (positive) component and an indirect (negative) component which depends strongly upon the effectiveness of each substance for ozone destruction. Generally, the halons are likely to have negative net GWPs, while those of the CFCs are likely to be positive over both 20- and 100-year time horizons (see Chapter 2, Table 2.8).

Executive Summary

Two important new findings since the IPCC WGI Second Assessment Report (IPCC, 1996) (hereafter SAR) demonstrate the importance of atmospheric chemistry in controlling greenhouse gases:

Currently, tropospheric ozone (O_3) is the third most important greenhouse gas after carbon dioxide (CO_2) and methane (CH_4). It is a product of photochemistry, and its future abundance is controlled primarily by emissions of CH_4, carbon monoxide (CO), nitrogen oxides (NO_x), and volatile organic compounds (VOC). There is now greater confidence in the model assessment of the increase in tropospheric O_3 since the pre-industrial period, which amounts to 30% when globally averaged, as well as the response to future emissions. For scenarios in which the CH_4 abundance doubles and anthropogenic CO and NO_x emissions triple, the tropospheric O_3 abundance is predicted to increase by an additional 50% above today's abundance.

CO is identified as an important indirect greenhouse gas. An addition of CO to the atmosphere perturbs the OH-CH_4-O_3 chemistry. Model calculations indicate that the emission of 100 Mt of CO stimulates an atmospheric chemistry perturbation that is equivalent to direct emission of about 5 Mt of CH_4.

A major conclusion of this report is that atmospheric abundances of almost all greenhouse gases reached the highest values in their measurement records during the 1990s:

The atmospheric abundance of CH_4 continues to increase, from about 1,520 ppb in 1978 to 1,745 ppb in 1998. However, the observed annual increase in CH_4 has declined during the last two decades. This increase is highly variable; it was near zero in 1992 and as large as +13 ppb during 1998. There is no clear, quantitative explanation for this variability. Since the SAR, quantification of certain anthropogenic sources of CH_4, such as that from rice production, has improved.

The atmospheric burden of nitrous oxide (N_2O) continues to increase by about 0.25%/yr. New, higher estimates of emissions from agricultural sources improve our understanding of the global N_2O budget.

The atmospheric abundances of major greenhouse gases that deplete stratospheric ozone are decreasing (CFC-11, CFC-113, CH_3CCl_3, CCl_4), or increasing more slowly (CFC-12), in response to the phase-out in their production agreed to under the Montreal Protocol and its Amendments.

HFC-152a and HFC-134a are increasing in the atmosphere. This growth is consistent with the rise in their industrial use. HFC-23, an unintended by-product of HCFC-22 production, is also increasing.

Perfluorocarbon (PFC) e.g., CF_4 (perfluoromethane) appears to have a natural background; however, current anthropogenic emissions exceed natural ones by a factor of 1,000 or more and are responsible for the observed increase.

There is good agreement between the increase in atmospheric abundances of sulphur hexafluoride (SF_6) and emissions estimates based on revised sales and storage data.

There has been little increase in global tropospheric O_3 since the 1980s at the few remote locations where it is regularly measured. Only two of the fourteen stations, one in Japan and one in Europe, had statistically significant increases in tropospheric O_3 between 1980 and 1995. By contrast, the four Canadian stations, all at high latitudes, had significant decreases in tropospheric O_3 for the same time period. However, limited observations from the late 19th and early 20th centuries combined with models suggest that tropospheric O_3 has increased from a global mean value of 25 DU (where 1 DU = 2.7×10^{16} O_3 molecules/cm^2) in the pre-industrial era to 34 DU today. While the SAR estimated similar values, the new analysis provides more confidence in this increase of 9 DU.

Changes in atmospheric composition and chemistry over the past century have affected, and those projected into the future will affect, the lifetimes of many greenhouse gases and thus alter the climate forcing of anthropogenic emissions:

The atmospheric lifetime relates emissions of a component to its atmospheric burden. In some cases, for instance for methane, a change in emissions perturbs the chemistry and thus the corresponding lifetime. The CH_4 feedback effect amplifies the climate forcing of an addition of CH_4 to the current atmosphere by lengthening the perturbation lifetime relative to the global atmospheric lifetime of CH_4 by a factor of 1.4. This earlier finding is corroborated here by new model studies that also predict only small changes in this CH_4 feedback for the different scenarios projected to year 2100. Another feedback has been identified for the addition of N_2O to the atmosphere; it is associated with stratospheric O_3 chemistry and shortens the perturbation lifetime relative to the global atmospheric lifetime of N_2O by about 5%.

Several chemically reactive gases – CO, NO_x (=NO+NO_2), and VOC – control in part the abundance of O_3 and the oxidising capacity (OH) of the troposphere. These pollutants act as indirect greenhouse gases through their influence on atmospheric chemistry, e.g., formation of tropospheric O_3 or changing the lifetime of CH_4. The emissions of NO_x and CO are dominated by human activities. The abundance of CO in the Northern Hemisphere is about twice that in the Southern Hemisphere and has increased in the second half of the 20th century along with industrialisation and population. The urban and regional abundance of NO_x has generally increased with industrialisation, but the global abundance of this short-lived, highly variable pollutant cannot be derived from measurements. Increased NO_x abundances will in general increase tropospheric O_3 and decrease CH_4. Deposition of NO_x reaction products fertilises the biosphere, stimulates CO_2 uptake, but also provides an input of acidic precipitation.

The IPCC Special Report on Emission Scenarios (SRES) generated six marker/illustrative scenarios (labelled A1B, A1T, A1FI, A2, B1, B2) plus four preliminary marker scenarios (labelled here A1p, A2p, B1p, and B2p). These projected changes in anthropogenic emissions of trace gases from year 2000 to year 2100, making different assumptions on population development, energy use, and technology. Results from both sets of scenarios are discussed here since the preliminary marker scenarios (December 1998) were used in this report:

Model calculations of the abundances of the primary greenhouse gases by year 2100 vary considerably across the SRES scenarios: in general A1B, A1T, and B1 have the smallest increases of emissions and burdens; and A1FI and A2 the largest. CH_4 changes from 1998 to 2100 range from −10 to +115%; and N_2O increases from 13 to 47%. The HFCs – 134a, 143a, and 125 – reach abundances of a few hundred to nearly a thousand ppt from negligible levels today. The PFC CF_4 is projected to increase to between 200 and 400 ppt; and SF_6 to between 35 and 65 ppt.

SRES projected anthropogenic emissions of the indirect greenhouse gases (NO_x, CO and VOC) together with changes in CH_4 are expected to change the global mean abundance of tropospheric OH by −20 to +6% over the next century. Comparable, but opposite sign, changes occur in the atmospheric lifetimes of the greenhouse gases, CH_4 and HFCs. This impact depends in large part on the magnitude of, and the balance between, NO_x and CO emissions.

For the SRES scenarios, changes in tropospheric O_3 between years 2000 and 2100 range from −4 to +21 DU. The largest increase predicted for the 21st century (scenarios A1FI and A2) would be more than twice as large as that experienced since the pre-industrial era. These O_3 increases are attributable to the concurrent, large (almost factor of 3) increases in anthropogenic NO_x and CH_4 emissions.

The large growth in emissions of greenhouse gases and other pollutants as projected in some SRES scenarios for the 21st century will degrade the global environment in ways beyond climate change:

Changes projected in the SRES A2 and A1FI scenarios would degrade air quality over much of the globe by increasing background levels of O_3. In northern mid-latitudes during summer, the zonal average increases near the surface are about 30 ppb or more, raising background levels to nearly 80 ppb, threatening attainment of air quality standards over most metropolitan and even rural regions, and compromising crop and forest productivity. This problem reaches across continental boundaries since emissions of NO_x influence photochemistry on a hemispheric scale.

A more complete and accurate assessment of the human impact on greenhouse gases requires greater understanding of sources, processes, and coupling between different parts of the climate system:

The current assessment is notably incomplete in calculating the total impact of individual industrial / agricultural sectors on greenhouse gases and aerosols. The IPCC Special Report on Aviation demonstrates that the total impact of a sector is not represented by (nor scalable to) the direct emissions of primary greenhouse gases alone, but needs to consider a wide range of atmospheric changes.

The ability to hindcast the detailed changes in atmospheric composition over the past decade, particularly the variability of tropospheric O_3 and CO, is limited by the availability of measurements and their integration with models and emissions data. Nevertheless, since the SAR there have been substantial advances in measurement techniques, field campaigns, laboratory studies, global networks, satellite observations, and coupled models that have improved the level of scientific understanding of this assessment. Better simulation of the past two decades, and in due course the upcoming one, would reduce uncertainty ranges and improve the confidence level of our projections of greenhouse gases.

Feedbacks between atmospheric chemistry, climate, and the biosphere were not developed to the stage that they could be included in the projected numbers here. Failure to include such coupling is likely to lead to systematic errors and may substantially alter the projected increases in the major greenhouse gases.

4.1 Introduction

This chapter investigates greenhouse gases whose atmospheric burdens[1] and climate impacts generally depend on atmospheric chemistry. These greenhouse gases include those listed in the Kyoto Protocol – methane (CH_4), nitrous oxide (N_2O), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), sulphur hexafluoride (SF_6) – and those listed under the Montreal Protocol and its Amendments – the chlorofluorocarbons (CFCs), the hydrochlorofluorocarbons (HCFCs), and the halons. A major focus of this assessment is the change in tropospheric ozone (O_3). Stratospheric water vapour (H_2O) is also treated here, but tropospheric H_2O, which is part of the hydrological cycle and calculated within climate models, is not discussed. This chapter also treats the reactive gases carbon monoxide (CO), volatile organic compounds (VOC), and nitrogen oxides (NO_x = $NO+NO_2$), termed indirect greenhouse gases. These pollutants are not significant direct greenhouse gases, but through atmospheric chemistry they control the abundances[1] of direct greenhouse gases. This chapter reviews the factors controlling the current atmospheric abundances of direct and indirect greenhouse gases; it looks at the changes since the pre-industrial era and their attribution to anthropogenic activities; and it calculates atmospheric abundances to the year 2100 based on projected emissions of greenhouse gases and pollutants. Carbon dioxide (CO_2) is treated in Chapter 3; and aerosols in Chapter 5. The atmospheric abundances of greenhouse gases and aerosols from all chapters are combined in Chapter 6 to calculate current and future radiative forcing. This chapter is an update of the IPCC WGI Second Assessment Report (IPCC, 1996) (hereafter SAR). For a review of the chemical processes controlling the abundance of greenhouse gases see the SAR (Prather *et al.*, 1995) or Ehhalt (1999). More recent assessments of changing atmospheric chemistry and composition include the IPCC Special Report on Aviation and the Global Atmosphere (Penner *et al.*, 1999) and the World Meteorological Organization / United Nations Environmental Programme (WMO/UNEP) Scientific Assessment of Ozone Depletion (WMO, 1999).

4.1.1 Sources of Greenhouse Gases

Substantial, pre-industrial abundances for CH_4 and N_2O are found in the tiny bubbles of ancient air trapped in ice cores. Both gases have large, natural emission rates, which have varied over past climatic changes but have sustained a stable atmospheric abundance for the centuries prior to the Industrial Revolution (see Figures 4.1 and 4.2). Emissions of CH_4 and N_2O due to human activities are also substantial and have caused large relative increases in their respective burdens over the last century. The atmospheric burdens of CH_4 and N_2O over the next century will likely be driven by changes in both anthropogenic and natural sources. A second class of greenhouse gases – the synthetic HFCs, PFCs, SF_6, CFCs, and halons – did not exist in the atmosphere before the 20th century (Butler *et al.*, 1999). CF_4, a PFC, is detected in ice cores and appears to have an extremely small natural source (Harnisch and Eisenhauer, 1998). The current burdens of these latter gases are derived from atmospheric observations and represent accumulations of past anthropogenic releases; their future burdens depend almost solely on industrial production and release to the atmosphere. Stratospheric H_2O could increase, driven by *in situ* sources, such as the oxidation of CH_4 and exhaust from aviation, or by a changing climate.

Tropospheric O_3 is both generated and destroyed by photochemistry within the atmosphere. Its *in situ* sources are expected to have grown with the increasing industrial emissions of its precursors: CH_4, NO_x, CO and VOC. In addition, there is substantial transport of ozone from the stratosphere to the troposphere (see also Section 4.2.4). The effects of stratospheric O_3 depletion over the past three decades and the projections of its recovery, following cessation of emissions of the Montreal Protocol gases, was recently assessed (WMO, 1999).

The current global emissions, mean abundances, and trends of the gases mentioned above are summarised in Table 4.1a. Table 4.1b lists additional synthetic greenhouse gases without established atmospheric abundances. For the Montreal Protocol gases, political regulation has led to a phase-out of emissions that has slowed their atmospheric increases, or turned them into decreases, such as for CFC-11. For other greenhouse gases, the anthropogenic emissions are projected to increase or remain high in the absence of climate-policy regulations. Projections of future emissions for this assessment, i.e., the IPCC Special Report on Emission Scenarios (SRES) (Nakićenović *et al.*, 2000) anticipate future development of industries and agriculture that represent major sources of greenhouse gases in the absence of climate-policy regulations. The first draft of this chapter and many of the climate studies in this report used the greenhouse gas concentrations derived from the SRES preliminary marker scenarios (i.e., the SRES database as of January 1999 and labelled ‘p’ here). The scenario IS92a has been carried along in many tables to provide a reference of the changes since the SAR. The projections of greenhouse gases and aerosols for the six new SRES marker/illustrative scenarios are discussed here and tabulated in Appendix II.

An important policy issue is the complete impact of different industrial or agricultural sectors on climate. This requires aggregation of the SRES scenarios by sector (e.g., transportation) or sub-sector (e.g., aviation; Penner *et al.*, 1999), including not only emissions but also changes in land use or natural ecosystems. Due to chemical coupling, correlated emissions can have synergistic effects; for instance NO_x and CO from transportation produce regional O_3 increases. Thus a given sector may act through several channels on the future trends of greenhouse gases. In this chapter we will evaluate the data available on this subject in the current literature and in the SRES scenarios.

---

[1] Atmospheric *abundances* for trace gases are reported here as the mole fraction (molar mixing ratio) of the gas relative to dry air (ppm = 10^{-6}, ppb = 10^{-9}, ppt = 10^{-12}); whereas the *burden* is reported as the total mass of that gas in the atmosphere (e.g., Mt = Tg = 10^{12} g). For most trace gases in this chapter, the burden is based on the total weight of the molecule; for the N-containing gases, it includes only the mass of the N; and for some VOC budgets where noted, it includes only the mass of the C.

[a] All abundances are tropospheric molar mixing ratios in ppt (10^{-12})and trends are in ppt/yr unless superseded by units on line (ppb = 10^{-9}, ppm = 10^{-6}). Where possible, the 1998 values are global, annual averages and the trends are calculated for 1996 to 1998.

[b] GWPs are from Chapter 6 of this report and refer to the 100-year horizon values.

[c] Species with chemical feedbacks that change the duration of the atmospheric response; global mean atmospheric lifetime (LT) is given first followed by perturbation lifetime (PT). Values are taken from the SAR (Prather *et al.*, 1995; Schimel *et al.*, 1996) updated with WMO98 (Kurylo and Rodriguez, 1999; Prinn and Zander, 1999) and new OH-scaling, see text. Uncertainties in lifetimes have not changed substantially since the SAR.

[d] CO trend is very sensitive to the time period chosen. The value listed for 1996 to 1998, +6 ppb/yr, is driven by a large increase during 1998. For the period 1991 to 1999, the CO trend was –0.6 ppb/yr. CO is an indirect greenhouse gas: for comparison with CH_4 see this chapter; for GWP, see Chapter 6.

4.1.2 Atmospheric Chemistry and Feedbacks

All greenhouse gases except CO_2 and H_2O are removed from the atmosphere primarily by chemical processes within the atmosphere. Greenhouse gases containing one or more H atoms (e.g., CH_4, HFCs and HCFCs), as well as other pollutants, are removed primarily by the reaction with hydroxyl radicals (OH). This removal takes place in the troposphere, the lowermost part of the atmosphere, ranging from the surface up to 7 to 16 km depending on latitude and season and containing 80% of the mass of the atmosphere. The greenhouse gases N_2O, PFCs, SF_6, CFCs and halons do not react with OH in the troposphere. These gases are destroyed in the stratosphere or above, mainly by solar ultraviolet radiation (UV) at short wavelengths (<240 nm), and are long-lived. Because of the time required to transport these gases to the region of chemical loss, they have a minimum lifetime of about 20 years. CO_2 is practically inert in the atmosphere and does not directly influence the chemistry, but it has a small *in situ* source from the oxidation of CH_4, CO and VOC.

Tropospheric OH abundances depend on abundances of NO_x, CH_4, CO, VOC, O_3 and H_2O plus the amount of solar UV (>300 nm) that reaches the troposphere. As a consequence, OH varies widely with geographical location, time of day, and season. Likewise the local loss rates of all those gases reacting with OH also vary. Because of its dependence on CH_4 and other pollutants, tropospheric OH is expected to have changed since the pre-industrial era and to change again for future emission scenarios. For some of these gases other removal processes, such as photolysis or surface uptake, are also important; and the total sink of the gas is obtained by integrating over all such processes. The chemistry of tropospheric O_3 is closely tied to that of OH, and its abundance also varies with changing precursor emissions. The chemistry of the troposphere is also directly influenced by the stratospheric burden of O_3, climatic changes in temperature (T) and humidity (H_2O), as well as by interactions between tropospheric aerosols and trace gases. Such couplings provide a "feedback" between the climate change induced by increasing greenhouse gases and the concentration of these gases. Another feedback, internal to the chemistry, is the impact of CH_4 on OH and hence its own loss. These feedbacks are expected to be important for tropospheric O_3 and OH. Such chemistry-chemistry or climate-chemistry coupling has been listed under "indirect effects" in the SAR (Prather *et al.*, 1995; Schimel *et al.*, 1996).

This chapter uses 3-D chemistry-transport models (CTMs) to integrate the varying chemical processes over global conditions, to estimate their significance, and to translate the emission scenarios into abundance changes in the greenhouse gases CH_4, HFCs, and O_3. An extensive modelling exercise called OxComp (tropospheric oxidant model comparison) – involving model comparisons, sensitivity studies, and investigation of the IPCC SRES scenarios – was organised to support this report.

Stratospheric circulation and distribution of O_3 control the transport of the long-lived greenhouse gases to regions of photochemical loss as well as the penetration of solar UV into the atmosphere. At the same time, many of these gases (e.g., N_2O and CFCs) supply ozone-depleting radicals (e.g., nitric oxide (NO) and Cl) to the stratosphere, providing a feedback between the gas and its loss rate. Another consequence of the observed stratospheric ozone depletion is that tropospheric photochemical activity is expected to have increased, altering tropospheric OH and O_3. Climate change in the 21st century, including the radiative cooling of the stratosphere by increased levels of CO_2, is expected to alter stratospheric circulation and O_3, and, hence, the global mean loss rates of the long-lived gases. Some of these effects are discussed in WMO (1999) and are briefly considered here.

The biosphere's response to global change will impact the atmospheric composition of the 21st century. The anticipated changes in climate (e.g., temperature, precipitation) and in chemistry will alter ecosystems and thus the "natural", background emissions of trace gases. There is accumulating evidence that increased N deposition (the result of NO_x and ammonia (NH_3) emissions) and elevated surface O_3 abundances have opposite influences on plant CO_2 uptake: O_3 (>40 ppb) inhibits CO_2 uptake; while N deposition enhances it up to a threshold, above which the effects are detrimental. In addition, the increased N availability from atmospheric deposition and direct fertilisation accelerates the emission of N-containing trace gases (NO, N_2O and NH_3) and CH_4, as well as altering species diversity and biospheric functioning. These complex interactions represent a chemistry-biosphere feedback that may alter greenhouse forcing.

4.1.3 Trace Gas Budgets and Trends

The "budget" of a trace gas consists of three quantities: its global source, global sink and atmospheric burden. The burden is defined as the total mass of the gas integrated over the atmosphere and related reservoirs, which usually include just the troposphere and stratosphere. The global burden (in Tg) and its trend (i.e., the difference between sources and sinks, in Tg/yr) can be determined from atmospheric measurements and, for the long-lived gases, are usually the best-known quantities in the budgets. For short-lived, highly variable gases such as tropospheric O_3 and NO_x, the atmospheric burden cannot be measured with great accuracy. The global source strength is the sum of all sources, including emissions and *in situ* chemical production. Likewise, the sink strength (or global loss rate) can have several independent components.

The source strength (Tg/yr) for most greenhouse gases is comprised of surface emissions. For synthetic gases where industrial production and emissions are well documented, the source strengths may be accurately known. For CH_4 and N_2O, however, there are large, not well-quantified, natural emissions. Further, the anthropogenic emissions of these gases are primarily associated with agricultural sources that are difficult to quantify accurately. Considerable research has gone into identifying and quantifying the emissions from individual sources for CH_4 and N_2O, as discussed below. Such uncertainty in source strength also holds for synthetic gases with undocumented emissions. The source strength for tropospheric O_3 includes both a stratospheric influx and *in situ* production and is thus derived primarily from global chemical models.

The sink strength (Tg/yr) of long-lived greenhouse gases can be derived from a combination of atmospheric observations, laboratory experiments, and models. The atmospheric chemistry models are based on physical principles and laboratory data, and include as constraints the observed chemistry of the atmosphere over the past two decades. For example, stratospheric loss rates are derived from models either by combining observed trace gas distributions with theoretically calculated loss frequencies or from the measured correlation of the respective gas with a trace gas of known vertical flux. In such analyses there are a wide range of self-consistency checks. Mean global loss rates based on *a priori* modelling (e.g., the CH_4-lifetime studies from OxComp described later) can be compared with empirically-based loss rates that are scaled from a gas with similar loss processes that has well-known emissions and atmospheric burden (e.g., the AGAGE (Advanced Global Atmospheric Gases Experiment) calibration of mean tropospheric OH using methyl chloroform (CH_3CCl_3); Prinn *et al.*, 1995). Our knowledge of the current budget of a greenhouse gas provides a key constraint in modelling its future abundance. For example, in both the IS92a and SRES projected emissions of CH_4 and N_2O, we apply a constant offset to each set of emissions so that our calculated burden is consistent with the observed budget and trend during the 1990s.

4.1.4 Atmospheric Lifetimes and Time-Scales

The global atmospheric lifetime (yr) characterises the time required to turn over the global atmospheric burden. It is defined as the burden (Tg) divided by the mean global sink (Tg/yr) for a gas in steady state (i.e., with unchanging burden). This quantity was defined as both "lifetime" and "turnover time" in the SAR (see also Bolin and Rodhe, 1973). Lifetimes calculated in this manner are listed in Table 4.1. A corollary of this definition is that, when in steady state (i.e., source strength = sink strength), the atmospheric burden of a gas equals the product of its lifetime and its emissions. A further corollary is that the integrated atmospheric abundance following a single emission is equal to the product of its steady-state lifetime for that emission pattern and the amount emitted (Prather, 1996). This latter, new result since the SAR supports the market-basket approach of aggregating the direct emissions of different greenhouse gases with a GWP (Global Warming Potential) weighting.

The atmospheric lifetime is basically a scale factor relating (i) constant emissions (Tg/yr) to a steady-state burden (Tg), or (ii) an emission pulse (Tg) to the time-integrated burden of that pulse (Tg/yr). The lifetime is often additionally assumed to be a constant, independent of the sources; and it is also taken to represent the decay time (e-fold) of a perturbation. These latter assumptions apply rigorously only for a gas whose local chemical lifetime is constant in space and time, such as for the noble gas radon, whose lifetime is fixed by the rate of its radioactive decay. In such a case the mean atmospheric lifetime equals the local lifetime: the lifetime that relates source strength to global burden is exactly the decay time of a perturbation.

This general applicability of the atmospheric lifetime breaks down for those greenhouse gases and pollutants whose chemical losses vary in space and time. NO_x, for instance, has a local lifetime of <1 day in the lower troposphere, but >5 days in the upper troposphere; and both times are less than the time required for vertical mixing of the troposphere. In this case emission of NO_x into the upper troposphere will produce a larger atmospheric burden than the same emission into the lower troposphere. Consequently, the definition of the atmospheric lifetime of NO_x is not unique and depends on the location (and season) of its emissions. The same is true for any gas whose local lifetime is variable and on average shorter than about 0.5 year, i.e., the decay time of a north-south difference between hemispheres representing one of the longer time-scales for tropospheric mixing. The majority of greenhouse gases considered here have atmospheric lifetimes greater than 2 years, much longer than tropospheric mixing times; and hence their lifetimes are not significantly altered by the location of sources within the troposphere. When lifetimes are reported for gases in Table 4.1, it is assumed that the gases are uniformly mixed throughout the troposphere. This assumption is unlikely for gases with lifetimes <1 year, and reported values must be viewed only as approximations.

Some gases have chemical feedbacks that change their lifetimes. For example, the increasing CH_4 abundance leads to a longer lifetime for CH_4 (Prather *et al.*, 1995; Schimel *et al.*, 1996). A chemical feedback with opposite effect has been identified for N_2O where a greater N_2O burden leads to increases in stratospheric NO_x which in turn depletes mid-stratospheric ozone. This ozone loss enhances the UV, and as a consequence N_2O is photolysed more rapidly (Prather, 1998). Such feedbacks cause the time-scale of a perturbation, henceforth called perturbation lifetime (*PT*), to differ from the global atmospheric lifetime (*LT*). In the limit of small perturbations, the relation between the perturbation lifetime of a gas and its global atmospheric lifetime can be derived from a simple budget relationship as $PT = LT / (1 - s)$, where the sensitivity coefficient $s = \partial ln(LT) / \partial ln(B)$ and B = burden. Without a feedback on lifetime, $s = 0$, and *PT* is identical to *LT*. The product, *PT* times a sustained change in emission, gives the resulting change in the burden. The ratio of *PT/LT* adopted here for CH_4, 1.4, is based on recent model studies (see Section 4.4) and is consistent with the SAR results.

To evaluate the total greenhouse effect of a given gas molecule, one needs to know, first, how long it remains in the atmosphere and, second, how it interacts chemically with other molecules. This effect is calculated by injecting a pulse of that gas (e.g., 1 Tg) into the atmosphere and watching the added abundance decay as simulated in a CTM. This decay is represented by a sum of exponential functions, each with its own decay time. These exponential functions are the chemical modes of the linearised chemistry-transport equations of the CTM (Prather, 1996). In the case of a CH_4 addition, the longest-lived mode has an e-fold time of 12 years, close to the perturbation lifetime (*PT*) of CH_4, and carries most of the added burden. (This e-fold time was called the adjustment time in the SAR.) In the case of a CO addition, this same mode is also excited, but at a reduced amplitude (Prather, 1996; Daniel and Solomon, 1998). The pulse of added CO, by causing the concentration of OH to decrease and thus the lifetime of CH_4 to increase temporarily, causes a build-up of CH_4 while the added burden of CO persists. After the initial period of a few months defined by the CO photochemical lifetime, this built-up CH_4 then decays in the same manner as would a direct pulse of CH_4. Similarly, an addition of NO_x (e.g., from aviation; see Isaksen and Jackman, 1999) will excite this mode, but with a negative amplitude. Thus, changes in the emissions of short-lived gases can generate long-lived perturbations as shown in 3-D CTMs (Wild and Prather, 2000; Derwent *et al.*, 2001). Changes in tropospheric O_3 accompany the CH_4 decay on a 12 year time-scale as an inherent component of this mode, a key example of chemical coupling in the troposphere. Thus, any chemically reactive gas, whether a greenhouse gas or not, will produce some level of indirect greenhouse effect through its impact on atmospheric chemistry.

4.2 Trace Gases: Current Observations, Trends, and Budgets

4.2.1 Non-CO_2 Kyoto Gases

4.2.1.1 Methane (CH_4)

Methane's globally averaged atmospheric surface abundance in 1998 was 1,745 ppb (see Figure 4.1), corresponding to a total burden of about 4,850 Tg(CH_4). The uncertainty in the burden is small (±5%) because the spatial and temporal distributions of tropospheric and stratospheric CH_4 have been determined by extensive high-precision measurements and the tropospheric variability is relatively small. For example, the Northern Hemisphere CH_4 abundances average about 5% higher than those in the Southern Hemisphere. Seasonal variations, with a minimum in late summer, are observed with peak-to-peak amplitudes of about 2% at mid-latitudes. The average vertical gradient in the troposphere is negligible, but CH_4 abundances in the stratosphere decrease rapidly with altitude, e.g., to 1,400 ppb at 30 km altitude in the tropics and to 500 ppb at 30 km in high latitude northern winter.

The most important known sources of atmospheric methane are listed in Table 4.2. Although the major source terms of atmospheric CH_4 have probably been identified, many of the source strengths are still uncertain due to the difficulty in assessing the global emission rates of the biospheric sources, whose strengths are highly variable in space and time: e.g., local emissions from most types of natural wetland can vary by a few orders of magnitude over a few metres. Nevertheless, new approaches have led to improved estimates of the global emissions rates from some source types. For instance, intensive studies on emissions from rice agriculture have substantially improved these emissions estimates (Ding and Wang, 1996; Wang and Shangguan, 1996). Further, integration of emissions over a whole growth period (rather than looking at the emissions on individual days with different ambient temperatures) has lowered the estimates of CH_4 emissions from rice agriculture from about 80 Tg/yr to about 40 Tg/yr (Neue and Sass, 1998; Sass *et al.*, 1999). There have also been attempts to deduce emission rates from observed spatial and temporal distributions of atmospheric CH_4 through inverse modelling (e.g., Hein *et al.*, 1997; Houweling *et al.*, 1999). The emissions so derived depend on the precise knowledge of the mean global loss rate and represent a relative attribution into aggregated sources of similar properties. The results of some of these studies have been included in Table 4.2. The global CH_4 budget can also be constrained by measurements of stable isotopes ($\delta^{13}C$ and δD) and radiocarbon ($^{14}CH_4$) in atmospheric CH_4 and in CH_4 from the major sources (e.g., Stevens and Engelkemeir, 1988; Wahlen *et al.*, 1989; Quay *et al.*, 1991, 1999; Lassey *et al.*, 1993; Lowe *et al.*, 1994). So far the measurements of isotopic composition of CH_4 have served mainly to constrain the contribution from fossil fuel related sources. The emissions from the various sources sum up to a global total of about 600 Tg/yr, of which about 60% are related to human activities such as agriculture, fossil fuel use and waste disposal. This is consistent with the SRES estimate of 347 Tg/yr for anthropogenic CH_4 emissions in the year 2000.

The current emissions from CH_4 hydrate deposits appear small, about 10 Tg/yr. However, these deposits are enormous, about 10^7 TgC (Suess *et al.*, 1999), and there is an indication of a catastrophic release of a gaseous carbon compound about 55 million years ago, which has been attributed to a large-scale perturbation of CH_4 hydrate deposits (Dickens, 1999; Norris and Röhl, 1999). Recent research points to regional releases of CH_4 from clathrates in ocean sediments during the last 60,000 years (Kennett *et al.*, 2000), but much of this CH_4 is likely to be oxidised by bacteria before reaching the atmosphere (Dickens, 2001). This evidence adds to the concern that the expected global warming may lead to an increase in these emissions and thus to another positive feedback in the climate system. So far, the size of that feedback has not been quantified. On the other hand, the historic record of atmospheric CH_4 derived from ice cores (Petit *et al.*, 1999), which spans several large temperature swings plus glaciations, constrains the possible past releases from methane hydrates to the atmosphere. Indeed, Brook *et al.* (2000) find little evidence for rapid, massive CH_4 excursions that might be associated with large-scale decomposition of methane hydrates in sediments during the past 50,000 years.

The mean global loss rate of atmospheric CH_4 is dominated by its reaction with OH in the troposphere.

$$OH + CH_4 \quad \rightarrow \quad CH_3 + H_2O$$

This loss term can be quantified with relatively good accuracy based on the mean global OH concentration derived from the methyl chloroform (CH_3CCL_3) budget described in Section 4.2.6 on OH. In that way we obtain a mean global loss rate of 507 Tg(CH_4)/yr for the current tropospheric removal of CH_4 by OH. In addition there are other minor removal processes for atmospheric CH_4. Reaction with Cl atoms in the marine boundary layer probably constitutes less than 2% of the total sink (Singh *et al.*, 1996). A recent process model study (Ridgwell *et al.*, 1999) suggested a soil sink of 38 Tg/yr, and this can be compared to SAR estimates of 30 Tg/yr. Minor amounts of CH_4 are also destroyed in the stratosphere by reactions with OH, Cl, and $O(^1D)$, resulting in a combined loss rate of 40 Tg/yr. Summing these, our best estimate of the current global loss rate of atmospheric CH_4 totals 576 Tg/yr (see Table 4.2), which agrees reasonably with the total sources derived from process models. The atmospheric lifetime of CH_4 derived from this loss rate and the global burden is 8.4 years. Attributing individual lifetimes to the different components of CH_4 loss results in 9.6 years for loss due to tropospheric OH, 120 years for stratospheric loss, and 160 years for the soil sink (i.e., 1/8.4 yr = 1/9.6 yr + 1/120 yr + 1/160 yr).

The atmospheric abundance of CH_4 has increased by about a factor of 2.5 since the pre-industrial era (see Figure 4.1a) as evidenced by measurements of CH_4 in air extracted from ice cores and firn (Etheridge *et al.*, 1998). This increase still continues, albeit at a declining rate (see Figure 4.1b). The global tropospheric CH_4 growth rate averaged over the period 1992 through 1998 is about 4.9 ppb/yr, corresponding to an average annual increase in atmospheric burden of 14 Tg. Superimposed on this long-term decline in growth rate are interannual variations in the trend (Figure 4.1c). There are no clear quantitative explanations for this variability, but understanding these variations in

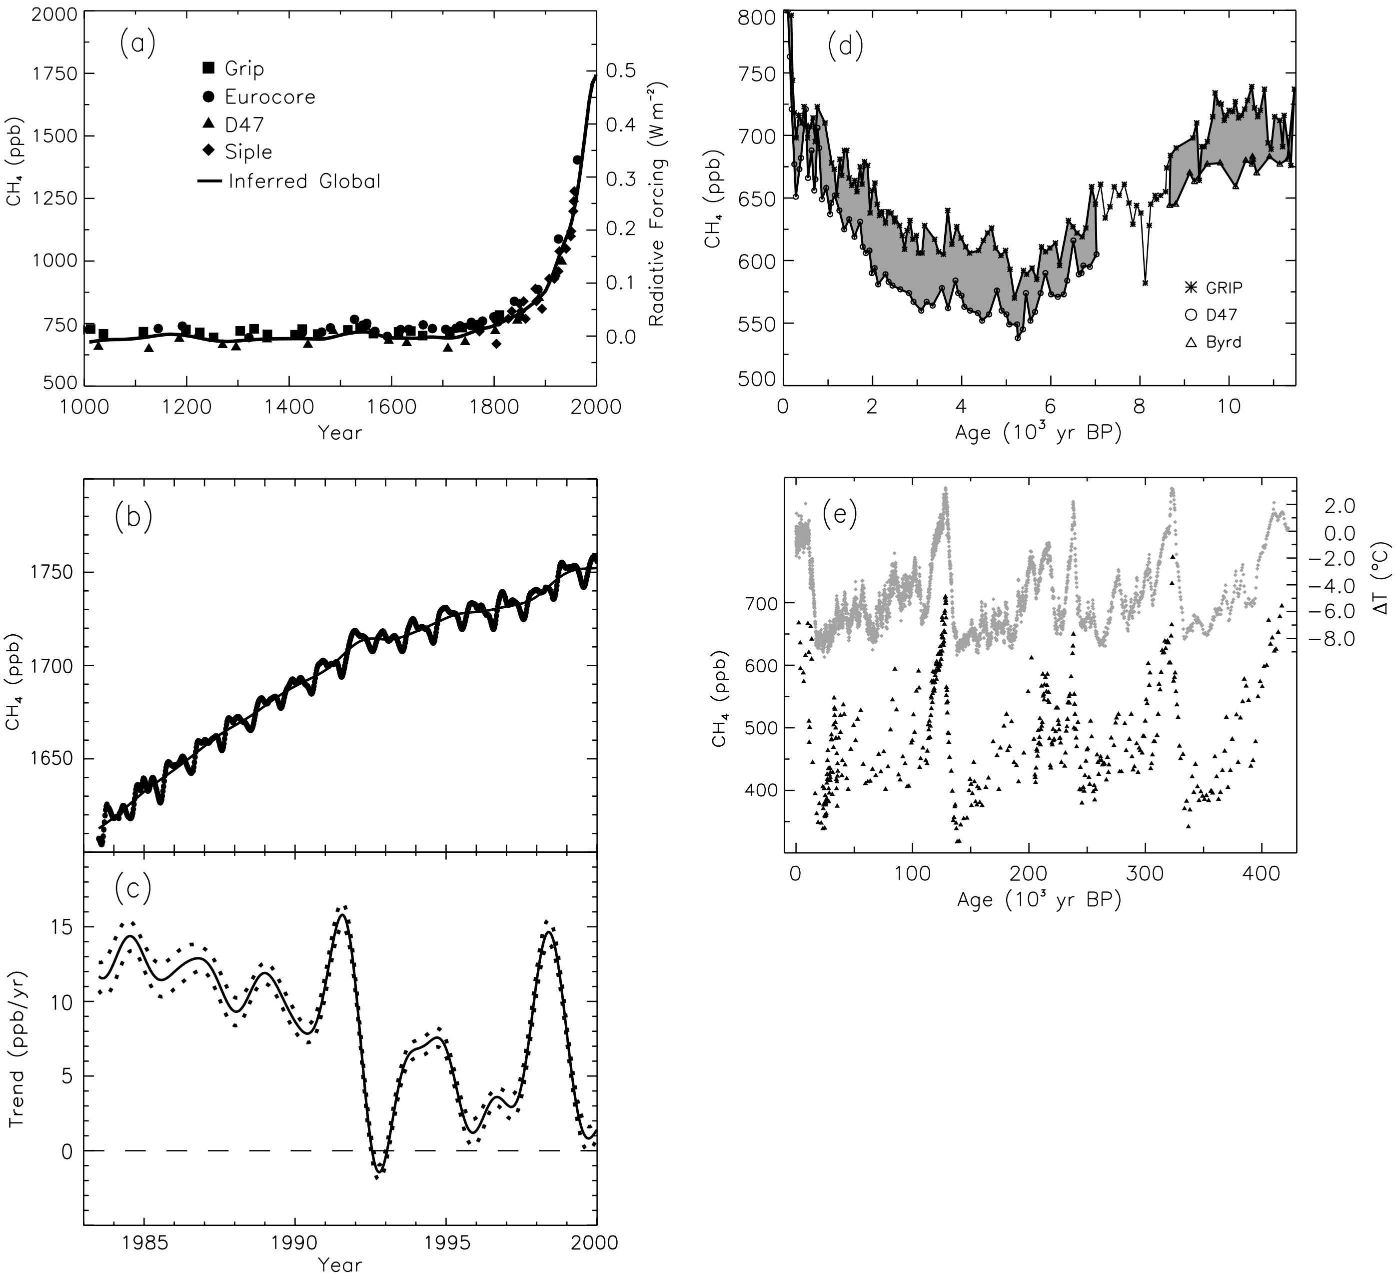

Figure 4.1: (a) Change in CH_4 abundance (mole fraction, in ppb = 10^{-9}) determined from ice cores, firn, and whole air samples plotted for the last 1,000 years. Data sets are as follows: Grip, Blunier *et al.* (1995) and Chappellaz *et al.* (1997); Eurocore, Blunier *et al.* (1993); D47, Chappellaz *et al.* (1997); Siple, Stauffer *et al.* (1985); Global (inferred from Antarctic and Greenland ice cores, firn air, and modern measurements), Etheridge *et al.* (1998) and Dlugokencky *et al.* (1998). Radiative forcing, approximated by a linear scale since the pre-industrial era, is plotted on the right axis. (b) Globally averaged CH_4 (monthly varying) and deseasonalised CH_4 (smooth line) abundance plotted for 1983 to 1999 (Dlugokencky *et al.*, 1998). (c) Instantaneous annual growth rate (ppb/yr) in global atmospheric CH_4 abundance from 1983 through 1999 calculated as the derivative of the deseasonalised trend curve above (Dlugokencky *et al.*, 1998). Uncertainties (dotted lines) are ±1 standard deviation. (d) Comparison of Greenland (GRIP) and Antarctic (D47 and Byrd) CH_4 abundances for the past 11.5 kyr (Chappellaz *et al.*, 1997). The shaded area is the pole-to-pole difference where Antarctic data exist. trend will ultimately help constrain specific budget terms. After the eruption of Mt. Pinatubo, a large positive anomaly in growth rate was observed at tropical latitudes. It has been attributed to short-term decreases in solar UV in the tropics immediately following the eruption that decreased OH formation rates in the troposphere (Dlugokencky *et al.*, 1996). A large decrease in growth was observed, particularly in high northern latitudes, in 1992. This feature has been attributed in part to decreased northern wetland emission rates resulting from anomalously low surface temperatures (Hogan and Harriss, 1994) and in part to

stratospheric ozone depletion that increased tropospheric OH (Bekki *et al.*, 1994; Fuglestvedt *et al.*, 1994). Records of changes in the $^{13}C/^{12}C$ ratios in atmospheric CH_4 during this period suggest the existence of an anomaly in the sources or sinks involving more than one causal factor (Lowe *et al.*, 1997; Mak *et al.*, 2000).

There is no consensus on the causes of the long-term decline in the annual growth rate. Assuming a constant mean atmospheric lifetime of CH_4 of 8.9 years as derived by Prinn *et al.* (1995), Dlugokencky *et al.* (1998) suggest that during the period 1984 to 1997 global emissions were essentially constant and that the decline in annual growth rate was caused by an approach to steady state between global emissions and atmospheric loss rate. Their estimated average source strength was about 550 Tg/yr. (Inclusion of a soil sink term of 30 Tg/yr would decrease the lifetime to 8.6 years and suggest an average source strength of about 570 Tg/yr.) Francey *et al.* (1999), using measurements of $^{13}CH_4$ from Antarctic firn air samples and archived air from Cape Grim, Tasmania, also concluded that the decreased CH_4 growth rate was consistent with constant OH and constant or very slowly increasing CH_4 sources after 1982. However, other analyses of the global methyl chloroform (CH_3CCl_3) budget (Krol *et al.*, 1998) and the changing chemistry of the atmosphere (Karlsdottir and Isaksen, 2000) argue for an increase in globally averaged OH of +0.5%/yr over the last two decades (see Section 4.2.6 below) and hence a parallel increase in global CH_4 emissions by +0.5%/yr.

The historic record of atmospheric CH_4 obtained from ice cores has been extended to 420,000 years before present (BP) (Petit *et al.*, 1999). As Figure 4.1e demonstrates, at no time during this record have atmospheric CH_4 mixing ratios approached today's values. CH_4 varies with climate as does CO_2. High values are observed during interglacial periods, but these maxima barely exceed the immediate pre-industrial CH_4 mixing ratio of 700 ppb. At the same time, ice core measurements from Greenland and Antarctica indicate that during the Holocene CH_4 had a pole-to-pole difference of about 44 ± 7 ppb with higher values in the Arctic as today, but long before humans influenced atmospheric methane concentrations (Chappelaz *et al.*, 1997; Figure 4.1d). Finally, study of CH_4 ice-core records at high time resolution reveals no evidence for rapid, massive CH_4 excursions that might be associated with large-scale decomposition of methane hydrates in sediments (Brook *et al.*, 2000).

The feedback of CH_4 on tropospheric OH and its own lifetime is re-evaluated with contemporary CTMs as part of OxComp, and results are summarised in Table 4.3. The calculated OH feedback, $\partial\ln(OH) / \partial\ln(CH_4)$, is consistent between the models, indicating that tropospheric OH abundances decline by 0.32% for every 1% increase in CH_4. The TAR value for the sensitivity coefficient $s = \partial\ln(LT) / \partial\ln(CH_4)$ is then 0.28 and the ratio PT/LT is 1.4. This 40% increase in the integrated effect of a CH_4 perturbation does not appear as a 40% larger amplitude in the perturbation but rather as a lengthening of the duration of the perturbation to 12 years. This feedback is difficult

[b] Lifetime against tropospheric OH loss at 1,745 ppb.

[c] Evaluated at 4,300 ppb CH_4 plus emissions for Y2100/draft-A2 scenario.

[d] TAR recommended OH lifetime for CH_4, 9.6 yr, is scaled from a CH_3CCl_3 OH lifetime of 5.7 yr (WMO, 1999; based on Prinn *et al.*, 1995) using a temperature of 272K (Spivakovsky *et al*., 2000). Stratospheric (120 yr) and soil-loss (160 yr) lifetimes are added (inversely) to give mean atmospheric lifetime of 8.4 yr. Only the OH lifetime is diagnosed and is subject to chemical feedback factor, and thus the total atmospheric lifetime for a CH_4 perturbation is 12 yr. In the SAR, the feedback factor referred only to the increase in the lifetime against tropospheric OH, and hence was larger. For Chemistry Transport Model (CTM) code see Table 4.10.

to observe, since it would require knowledge of the *increase* in CH_4 sources plus other factors affecting OH over the past two decades. Unlike for the global mean tropospheric OH abundance, there is also no synthetic compound that can calibrate this feedback; but it is possible that an analysis of the budgets of $^{13}CH_4$ and $^{12}CH_4$ separately may lead to an observational constraint (Manning, 1999).

4.2.1.2 Nitrous oxide (N_2O)

The globally averaged surface abundance of N_2O was 314 ppb in 1998, corresponding to a global burden of 1510 TgN. N_2O abundances are about 0.8 ppb greater in the Northern Hemisphere than in the Southern Hemisphere, consistent with about 60% of emissions occurring in the Northern Hemisphere. Almost no vertical gradient is observed in the troposphere, but N_2O abundances decrease in the stratosphere, for example, falling to about 120 ppb by 30 km at mid-latitudes.

The known sources of N_2O are listed in Table 4.4 with estimates of their emission rates and ranges. As with methane, it remains difficult to assess global emission rates from individual sources that vary greatly over small spatial and temporal scales. Total N_2O emissions of 16.4 TgN/yr can be inferred from the N_2O global sink strength (burden/lifetime) plus the rate of increase in the burden. In the SAR the sum of N_2O emissions from specific sources was notably less than that inferred from the loss rate. The recent estimates of global N_2O emissions from Mosier *et al.* (1998b) and Kroeze *et al.* (1999) match the global loss rate and underline the progress that has been made on quantification of natural and agricultural sources. The former study calculated new values for N_2O agricultural emissions that include the full impact of agriculture on the global nitrogen cycle and show that N_2O emissions from soils are the largest term in the budget (Table 4.4). The latter study combined these with emissions from other anthropogenic and natural sources to calculate a total emission of 17.7 TgN/yr for 1994.

The enhanced N_2O emissions from agricultural and natural ecosystems are believed to be caused by increasing soil N availability driven by increased fertilizer use, agricultural nitrogen (N_2) fixation, and N deposition; and this model can explain the increase in atmospheric N_2O abundances over the last 150 years (Nevison and Holland, 1997). Recent discovery of a faster-than-linear feedback in the emission of N_2O and NO from soils in response to external N inputs is important, given the projected increases of N fertilisation and deposition increases in tropical countries (Matson *et al.*, 1999). Tropical ecosystems, currently an important source of N_2O (and NO) are often phosphorus-limited rather than being N-limited like the Northern Hemispheric terrestrial ecosystems. Nitrogen fertiliser inputs into these phosphorus-limited ecosystems generate NO and N_2O fluxes that are 10 to 100 times greater than the same fertiliser addition to nearby N-limited ecosystems (Hall and Matson, 1999). In addition to N availability, soil N_2O emissions are regulated by temperature and soil moisture and so are likely to respond to climate changes (Frolking *et al.*, 1998; Parton *et al.*, 1998). The magnitude of this response will be affected by feedbacks operating through the biospheric carbon cycle (Li *et al.*, 1992, 1996).

The industrial sources of N_2O include nylon production, nitric acid production, fossil fuel fired power plants, and vehicular emissions. It was once thought that emission from

automobile catalytic converters were a potential source of N_2O, but extrapolating measurements of N_2O emissions from automobiles in roadway tunnels in Stockholm and Hamburg during 1992 to the global fleet gives a source of only 0.24 ± 0.14 TgN/yr (Berges *et al.*, 1993). More recent measurements suggest even smaller global emissions from automobiles, 0.11 ± 0.04 TgN/yr (Becker *et al.*, 1999; Jiménez *et al.*, 2000).

The identified sinks for N_2O are photodissociation (90%) and reaction with electronically excited oxygen atoms ($O(^1D)$); they occur in the stratosphere and lead to an atmospheric lifetime of 120 years (SAR; Volk *et al.*, 1997; Prinn and Zander, 1999). The small uptake of N_2O by soils is not included in this lifetime, but is rather incorporated into the net emission of N_2O from soils because it is coupled to the overall N-partitioning.

Isotopic ($\delta^{15}N$ and $\delta^{18}O$) N_2O measurements are also used to constrain the N_2O budget. The isotopic composition of tropospheric N_2O derives from the flux-weighted isotopic composition of sources corrected for fractionation during destruction in the stratosphere. Typical observed values are $\delta^{15}N = 7$ ‰ and $\delta^{18}O =$ 20.7 ‰ relative to atmospheric N_2 and oxygen (O_2) (Kim and Craig, 1990). Most surface sources are depleted in ^{15}N and ^{18}O relative to tropospheric N_2O (e.g., Kim and Craig, 1993), and so other processes (sources or sinks) must lead to isotopic enrichment. Rahn and Wahlen (1997) use stratospheric air samples to show that the tropospheric isotope signature of N_2O can be explained by a return flux of isotopically enriched N_2O from the stratosphere, and no exotic sources of N_2O are needed. Yung and Miller (1997) point out that large isotopic fractionation can occur in the stratosphere during photolysis due to small differences in the zero point energies of the different isotopic species, and Rahn *et al.* (1998) have verified this latter effect with laboratory measurements. Wingen and Finlayson-Pitts (1998) failed to find evidence that reaction of CO_3 with N_2 (McElroy and Jones, 1996) is an atmospheric source of N_2O. The use of isotopes has not yet conclusively identified new sources nor constrained the N_2O budget better than other approaches, but the emerging data set of isotopic measurements, including measurements of the intramolecular position of ^{15}N in N_2O isotopomers (Yoshida and Toyoda, 2000) will provide better constraints in the future.

Tropospheric N_2O abundances have increased from pre-industrial values of about 270 ppb (Machida *et al.*, 1995; Battle *et al.*, 1996; Flückiger *et al.*, 1999) to a globally averaged value of 314 ppb in 1998 (Prinn *et al.*, 1990, 1998; Elkins *et al.*, 1998) as shown in Figure 4.2. The pre-industrial source is estimated to

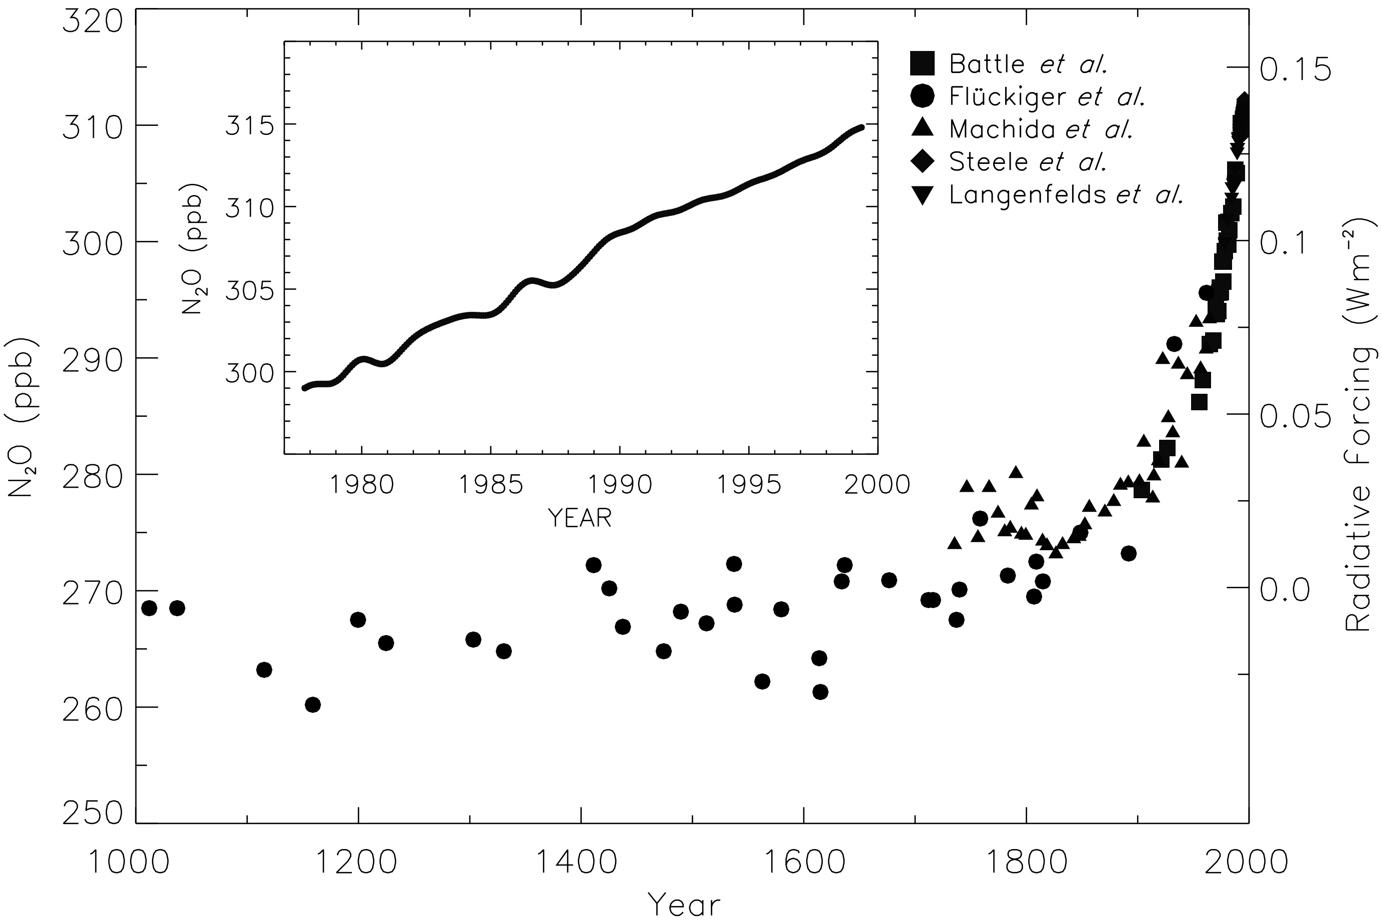

Figure 4.2: Change in N_2O abundance for the last 1,000 years as determined from ice cores, firn, and whole air samples. Data sets are from: Machida *et al.* (1995); Battle *et al.* (1996); Langenfelds *et al.* (1996); Steele *et al.* (1996); Flückiger *et al.* (1999). Radiative forcing, approximated by a linear scale, is plotted on the right axis. Deseasonalised global averages are plotted in the inset (Butler *et al.*, 1998b).

be 10.7 TgN/yr, which implies that current anthropogenic emissions are about 5.7 TgN/yr assuming no change in the natural emissions over this period. The average rate of increase during the period 1980 to 1998 determined from surface measurements was +0.8 ± 0.2 ppb/yr (+0.25 ± 0.05 %/yr) and is in reasonable agreement with measurements of the N_2O vertical column density above Jungfraujoch Station, +0.36 ± 0.06%/yr between 1984 and 1992 (Zander *et al.*, 1994). Large interannual variations in this trend are also observed. Thompson *et al.* (1994) report that the N_2O growth rate decreased from 1 ppb/yr in 1991 to 0.5 ppb/yr in 1993 and suggest that decreased use of nitrogen-containing fertiliser and lower temperatures in the Northern Hemisphere may have been in part responsible for lower biogenic soil emissions. Schauffler and Daniel (1994) suggest that the N_2O trend was affected by stratospheric circulation changes induced by massive increase in stratospheric aerosols following the eruption of Mt. Pinatubo. Since 1993, the N_2O increase has returned to rates closer to those observed during the 1980s.

The feedback of N_2O on its own lifetime (Prather, 1998) has been examined for this assessment with additional studies from established 2-D stratospheric chemical models. All models give similar results, see Table 4.5. The global mean atmospheric lifetime of N_2O decreases about 0.5% for every 10% increase in N_2O (s = –0.05). This shift is small but systematic, and it is included in Table 4.1a as a shorter perturbation lifetime for N_2O, 114 years instead of 120 years. For N_2O (unlike for CH_4) the time to mix the gas into the middle stratosphere where it is destroyed, about 3 years, causes a separation between PT (about 114 years) and the e-fold of the long-lived mode (about 110 years).

4.2.1.3 Hydrofluorocarbons (HFCs)

The HFCs with the largest measured atmospheric abundances are (in order), HFC-23 (CHF_3), HFC-134a (CF_3CH_2F), and HFC-152a (CH_3CHF_2). The recent rises in these HFCs are shown in Figure 4.3 along with some major HCFCs, the latter being controlled under the Montreal Protocol and its Amendments. HFC-23 is a by-product of HCFC-22 production. It has a long atmospheric lifetime of 260 years, so that most emissions, which have occurred over the past two decades, will have accumulated in the atmosphere. Between 1978 and 1995, HFC-23 increased from about 3 to 10 ppt; and it continues to rise even more rapidly (Oram *et al.*, 1996). HFC-134a is used primarily as a refrigerant, especially in car air conditioners. It has an atmospheric lifetime of 13.8 years, and its annual emissions have grown from near

Table 4.5: *Nitrous oxide lifetime feedback and residence time.*

Models	**Contributor**	**Lifetime LT** (yr)	**Sensitivity,** $s=\partial \ln(LT)/\partial \ln(B)$	**Decay Time of mode** (yr)
AER 2D	Ko and Weisenstein	111	–0.062	102
GSFC 2D	Jackman	137	–0.052	127
UCI 1D	Prather	119	–0.046	110
Oslo 2D	Rognerud	97	–0.061	

Lifetime (LT_B) is calculated at steady-state for an N_2O burden (B) corresponding to a tropospheric abundance of 330 ppb. The sensitivity coefficient (s) is calculated by increasing the N_2O burden approximately 10% to B+ΔB, calculating the new steady state atmospheric lifetime ($LT_{B+\Delta B}$), and then using a finite difference approximation for s, $\ln(LT_{B+\Delta B}/LT_B)/\ln(1+\Delta B/B)$. The perturbation lifetime (PT), i.e., the effective duration of an N_2O addition, can be derived as $PT = LT/(1-s)$ or equivalently from the simple budget-balance equation: $(B+\Delta B)/LT_{B+\Delta B} = B/LT_B + \Delta B/PT$.

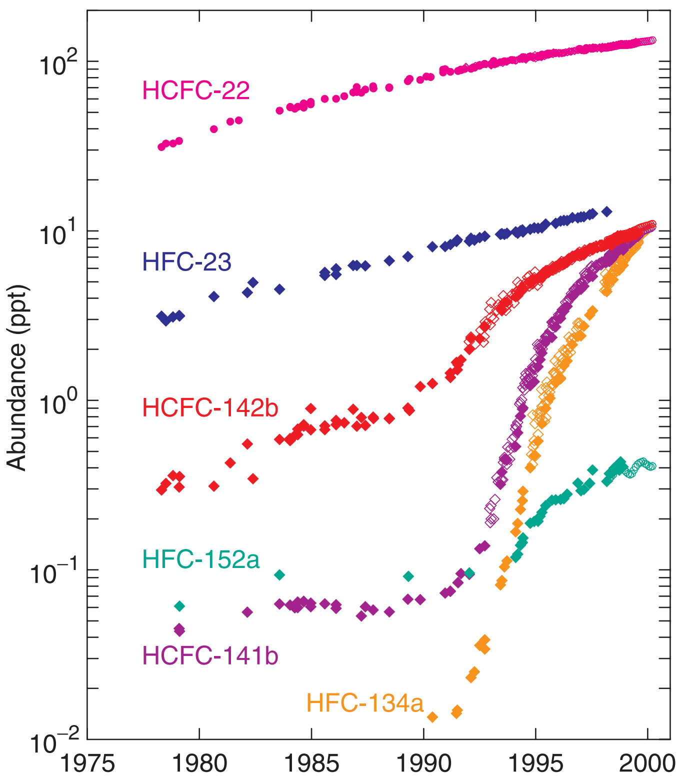

Figure 4.3: HFC-23 (blue, UEA scale), -152a (green, UEA scale), -134a (orange, NOAA scale), and HCFC-22 (magenta, SIO scale), -142b (red, NOAA scale), and -141b (purple, NOAA scale) abundances (ppt) at Cape Grim, Tasmania for the period 1978 to 1999. Different symbols are data from different measurement networks: SIO (filled circles), NOAA-CMDL (open diamonds, Montzka *et al.*, 1994, 1996a,b, 1999), UEA (filled diamonds, Oram *et al.*, 1995, 1996, 1998, 1999) and AGAGE (open circles, only for 1998 to 2000, all gases but HFC-23, Miller *et al.*, 1998; Sturrock *et al.*, 1999; Prinn *et al.*, 2000). Southern Hemisphere values (Cape Grim) are slightly lower than global averages.

zero in 1990 to an estimated 0.032 Tg/yr in 1996. The abundance continues to rise almost exponentially as the use of this HFC increases (Montzka *et al.*, 1996b; Oram *et al.*, 1996; Simmonds *et al.*, 1998). HFC-152a is a short-lived gas with a mean atmospheric lifetime of 1.4 years. Its rise has been steady, but its low emissions and a short lifetime have kept its abundance below 1 ppt.

4.2.1.4 Perfluorocarbons (PFCs) and sulphur hexafluoride (SF_6)

PFCs, in particular CF_4 and C_2F_6, as well as SF_6 have sources predominantly in the Northern Hemisphere, atmospheric lifetimes longer than 1,000 years, and large absorption cross-sections for terrestrial infra-red radiation. These compounds are far from a steady state between sources and sinks, and even small emissions will contribute to radiative forcing over the next several millennia. Current emissions of C_2F_6 and SF_6 are clearly anthropogenic and well quantified by the accumulating atmospheric burden. Harnisch and Eisenhauer (1998) have shown that CF_4 and SF_6 are naturally present in fluorites, and out-gassing from these materials leads to natural background abundances of 40 ppt for CF_4 and 0.01 ppt for SF_6. However, at present the anthropogenic emissions of CF_4 exceed the natural ones by a factor of 1,000 or more and are responsible for the rapid rise in atmospheric abundance. Atmospheric burdens of CF_4 and SF_6 are increasing as shown in Figures 4.4 and 4.5, respectively. Surface measurements show that SF_6 has increased by about 7%/yr during the 1980s and 1990s (Geller *et al.*, 1997; Maiss and Brenninkmeijer, 1998). Recent relative rates of increase are 1.3%/yr for CF_4 and 3.2%/yr for C_2F_6 (Harnisch *et al.*, 1996). The only important sinks for PFCs and SF_6 are photolysis or ion reactions in the mesosphere. These gases provide useful tracers of atmospheric transport in both troposphere and stratosphere.

A new, long-lived, anthropogenic greenhouse gas has recently been found in the atmosphere (Sturges *et al.*, 2000). Trifluoromethyl sulphur pentafluoride (SF_5CF_3) – a hybrid of PFCs and SF_6 not specifically addressed in Annex A of the Kyoto Protocol – has the largest radiative forcing, on a per molecule basis, of any gas found in the atmosphere to date. Its abundance has grown from near zero in the late 1960s to about 0.12 ppt in 1999.

4.2.2 Montreal Protocol Gases and Stratospheric Ozone (O_3)

The Montreal Protocol is an internationally accepted agreement whereby nations agree to control the production of ozone-depleting substances. Many of the chemicals that release chlorine atoms into the stratosphere, and deplete stratospheric O_3, are also greenhouse gases, so they are discussed briefly here. Detailed assessment of the current observations, trends, lifetimes, and emissions for substances covered by the protocol are in WMO (Kurylo and Rodriguez, 1999; Prinn and Zander, 1999). The ozone-depleting gases with the largest potential to influence climate are CFC-11 ($CFCl_3$), CFC-12 (CF_2Cl_2), and CFC-113 ($CF_2ClCFCl_2$). It is now clear from measurements in polar firn air that there are no natural sources of these compounds (Butler *et al.*, 1999). Surface measurements of these compounds show that their growth rates continue to decline. Growth rates are slightly negative for CFC-11 and CFC-113 (Montzka *et al.*, 1996a, 1999; Prinn *et al.*, 2000); see Figure 4.6. CFC-12 increased by 4 ppt/yr during 1995 to 1996, down from about 12 ppt/yr in the late 1980s, see Figure 4.7). Methyl chloroform (CH_3CCl_3) has decreased dramatically since the Montreal Protocol was invoked, due to its relatively short lifetime (about 5 years) and the rapidity with which emissions were phased out. Its decline was 13 ppt/yr during the period 1995 to 1996 (Prinn *et al.*, 1998, 2000). The halon abundances are small relative to the CFCs, and will never become large if the Montreal Protocol is adhered to. Atmospheric measurements show that growth rates of halon-1301 and halon-2402 decreased in response to the Montreal Protocol, but halon-1211 continues to increase at rates larger than expected based on industrial emissions data (Butler *et al.*, 1998a; Fraser *et al.*, 1999; Montzka *et al.*, 1999).

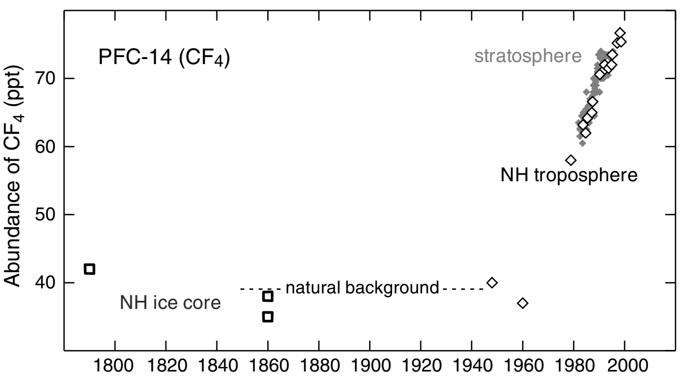

Figure 4.4: Abundance of CF_4 (ppt) over the last 200 years as measured in tropospheric air (open diamonds), stratospheric air (small filled diamonds), and ice cores (open squares) (Harnisch *et al.*, 1996; 1999).

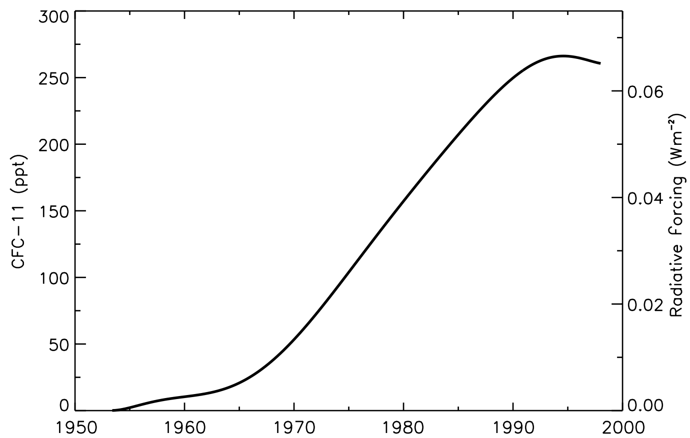

Figure 4.6: Global mean CFC-11 ($CFCl_3$) tropospheric abundance (ppt) from 1950 to 1998 based on smoothed measurements and emission models (Prinn *et al.*, 2000). CFC-11's radiative forcing is shown on the right axis.

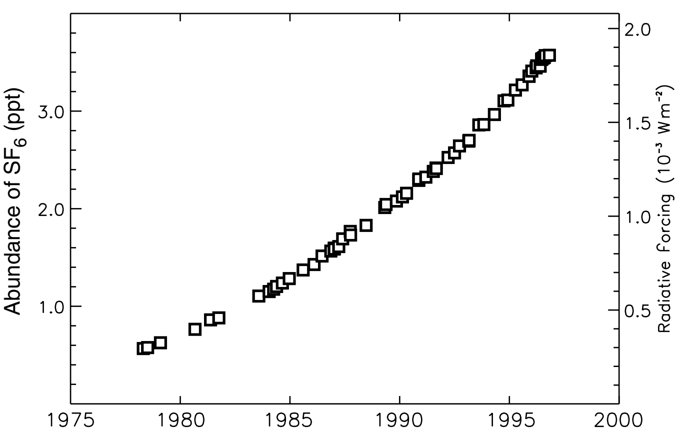

Figure 4.5: Abundance of SF_6 (ppt) measured at Cape Grim, Tasmania since 1978 (Maiss *et al.*, 1996; Maiss and Brenninkmeijer, 1998). Cape Grim values are about 3% lower than global averages.

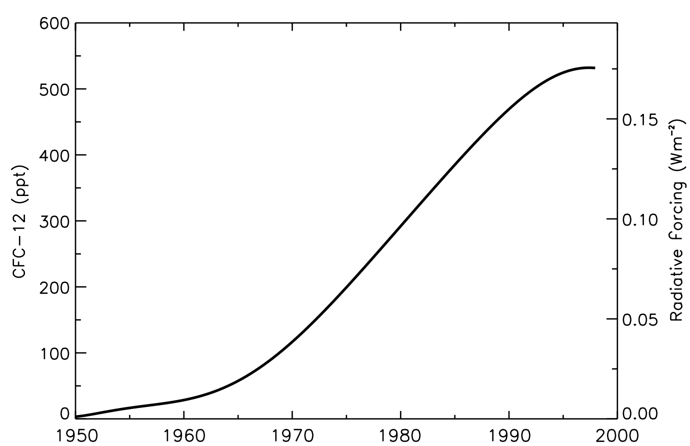

Figure 4.7: Global mean CFC-12 (CF_2Cl_2) tropospheric abundance (ppt) from 1950 to 1998 based on smoothed measurements and emission models (Prinn *et al.*, 2000). CFC-12's radiative forcing is shown on the right axis.

The depletion of stratospheric ozone over the past three decades has been substantial. Between 60°S and 60°N it averaged about 2%/decade. A thorough review of the direct and possible indirect effects of stratospheric ozone depletion are given in WMO (Granier and Shine, 1999). The depletion of O_3 (and its radiative forcing) is expected to follow the weighted halogen abundance in the stratosphere. Therefore, both will reach a maximum in about 2000 before starting to recover; however, detection of stratospheric O_3 recovery is not expected much before 2010 (Jackman *et al.*, 1996; Hofmann and Pyle, 1999). Methyl chloroform has been the main driver of the rapid turnaround in stratospheric chlorine during the late 1990s (Montzka *et al.*, 1999; Prinn *et al.*, 2000), and further recovery will rely on the more slowly declining abundances of CFC-11 and -12, and halons (Fraser *et al.*, 1999; Montzka *et al.*, 1999). It is expected that stratospheric ozone depletion due to halogens will recover during the next 50 to 100 years (Hofmann and Pyle, 1999). In the short run, climatic changes, such as cooling in the northern winter stratosphere, may enhance ozone depletion, but over the next century, the major uncertainties in stratospheric ozone lie with (i) the magnitude of future consumption of ozone-depleting substances by developing countries (Fraser and Prather, 1999; Montzka *et al.*, 1999), (ii) the projected abundances of CH_4 and N_2O, and (iii) the projected climate change impacts on stratospheric temperatures and circulation.

4.2.3 Reactive Gases

4.2.3.1 Carbon monoxide (CO) and hydrogen (H_2)

Carbon monoxide (CO) does not absorb terrestrial infrared radiation strongly enough to be counted as a direct greenhouse gas, but its role in determining tropospheric OH indirectly affects the atmospheric burden of CH_4 (Isaksen and Hov, 1987) and can lead to the formation of O_3. More than half of atmospheric CO emissions today are caused by human activities, and as a result the Northern Hemisphere contains about twice as much CO as the Southern Hemisphere. Because of its relatively short lifetime and distinct emission patterns, CO has large gradients in the atmosphere, and its global burden of about 360 Tg is more uncertain than those of CH_4 or N_2O. In the high northern latitudes, CO abundances vary from about 60 ppb during summer to 200 ppb during winter. At the South Pole, CO varies between about 30 ppb in summer and 65 ppb in winter. Observed abundances, supported by column density measurements, suggest that globally, CO was slowly increasing until the late 1980s, but has started to decrease since then (Zander *et al.* 1989; Khalil and Rasmussen, 1994), possibly due to decreased automobile emissions as a result of catalytic converters (Bakwin *et al.*, 1994). Measurements from a globally distributed network of sampling sites indicate that CO decreased globally by about 2 %/yr from 1991 to 1997 (Novelli *et al.*, 1998) but then increased in 1998. In the Southern Hemisphere, no long-term trend has been detected in CO measurements from Cape Point, South Africa for the period 1978 to 1998 (Labuschagne *et al.*, 1999).

Some recent evaluations of the global CO budget are presented in Table 4.6. The emissions presented by Hauglustaine *et al.* (1998) were used in a forward, i.e., top-down, modelling study of the CO budget; whereas Bergamasschi *et al.* (2000) used a model inversion to derive CO sources. These varied approaches do not yet lead to a consistent picture of the CO budget. Anthropogenic sources (deforestation, savanna and waste burning, fossil and domestic fuel use) dominate the direct emissions of CO, emitting 1,350 out of 1,550 Tg(CO)/yr. A source of 1,230 Tg(CO)/yr is estimated from *in situ* oxidation of CH_4 and other hydrocarbons, and about half of this source can be attributed to anthropogenic emissions. Fossil sources of CO have already been accounted for as release of fossil C in the CO_2 budget, and thus we do not double-count this CO as a source of CO_2.

It has been proposed that CO emissions should have a GWP because of their effects on the lifetimes of other greenhouse gases (Shine *et al.*, 1990; Fuglesvedt *et al.*, 1996; Prather, 1996). Daniel and Solomon (1998) estimate that the cumulative indirect radiative forcing due to anthropogenic CO emissions may be larger than that of N_2O. Combining these early box models with 3-D global CTM studies using models from OxComp (Wild and Prather, 2000; Derwent *et al.*, 2001) suggests that emitting 100 Tg(CO) is equivalent to emitting 5 Tg(CH_4): the resulting CH_4 perturbation appears after a few months and lasts 12 years as would a CH_4 perturbation; and further, the resulting tropospheric O_3 increase is global, the same as for a direct CH_4 perturbation. Effectively the CO emission excites the global 12-year chemical mode that is associated with CH_4 perturbations. This equivalency is not unique as the impact of CO appears to vary by as much as 20% with latitude of emission. Further, this equivalency systematically underestimates the impact of CO on greenhouse gases because it does not include the short-term tropospheric O_3 increase during the early period of very high CO abundances (< 6 months). Such O_3 increases are regional, however, and their magnitude depends on local conditions.

Molecular hydrogen (H_2) is not a direct greenhouse gas. But it can reduce OH and thus indirectly increase CH_4 and HFCs. Its atmospheric abundance is about 500 ppb. Simmonds *et al.* (2000) report a trend of +1.2 ± 0.8 ppb/yr for background air at Mace Head, Ireland between 1994 and 1998; but, in contrast, Novelli *et al.* (1999) report a trend of –2.3 ± 0.1 ppb/yr based on a global network of sampling sites. H_2 is produced in many of the same processes that produce CO (e.g., combustion of fossil fuel and atmospheric oxidation of CH_4), and its atmospheric measurements can be used to constrain CO and CH_4 budgets. Ehhalt (1999) estimates global annual emissions of about 70 Tg(H_2)/yr, of which half are anthropogenic. About one third of atmospheric H_2 is removed by reaction with tropospheric OH, and the remainder, by microbial uptake in soils. Due to the larger land area in the Northern Hemisphere than in the Southern Hemisphere, most H_2 is lost in the Northern Hemisphere. As a result, H_2 abundances are on average greater in the Southern Hemisphere despite 70% of emissions being in the Northern Hemisphere (Novelli *et al.*, 1999; Simmonds *et al.*, 2000). Currently the impact of H_2 on tropospheric OH is small, comparable to some of the VOC. No scenarios for changing H_2 emissions are considered here; however, in a possible fuel-cell economy, future emissions may need to be considered as a potential climate perturbation.

4.2.3.2 Volatile organic compounds (VOC)

Volatile organic compounds (VOC), which include non-methane hydrocarbons (NMHC) and oxygenated NMHC (e.g., alcohols, aldehydes and organic acids), have short atmospheric lifetimes (fractions of a day to months) and small direct impact on radiative forcing. VOC influence climate through their production of organic aerosols and their involvement in photochemistry, i.e., production of O_3 in the presence of NO_x and light. The largest source, by far, is natural emission from vegetation. Isoprene, with the largest emission rate, is not stored in plants and is only emitted during photosynthesis (Lerdau and Keller, 1997). Isoprene emission is an important component in tropospheric photochemistry (Guenther *et al.*, 1995, 1999) and is included in the OxComp simulations. Monoterpenes are stored in plant reservoirs, so they are emitted throughout the day and night. The monoterpenes play an important role in aerosol formation and are discussed in Chapter 5. Vegetation also releases other VOC at relatively small rates, and small amounts of NMHC are emitted naturally by the oceans. Anthropogenic sources of VOC include fuel production, distribution, and combustion, with the largest source being emissions (i) from motor vehicles due to either evaporation or incomplete combustion of fuel, and (ii) from biomass burning. Thousands of different compounds with varying lifetimes and chemical behaviour have been observed in the atmosphere, so most models of tropospheric chemistry include some chemical speciation of the VOC. Generally, fossil

wt% values are given for the individual VOC with the sums being: industrial, 210 Tg(VOC)/yr, corresponding to 161 TgC/yr; and biomass burning, 42 Tg(VOC)/yr, corresonding to 33 TgC/yr.

VOC sources have already been accounted for as release of fossil C in the CO_2 budgets and thus we do not count VOC as a source of CO_2.

Given their short lifetimes and geographically varying sources, it is not possible to derive a global atmospheric burden or mean abundance for most VOC from current measurements. VOC abundances are generally concentrated very near their sources. Natural emissions occur predominantly in the tropics (23°S to 23°N) with smaller amounts emitted in the northern mid-latitudes and boreal regions mainly in the warmer seasons. Anthropogenic emissions occur in heavily populated, industrialised regions (95% in the Northern Hemisphere peaking at 40°N to 50°N), where natural emissions are relatively low, so they have significant impacts on regional chemistry despite small global emissions. A few VOC, such as ethane and acetone, are longer-lived and impact tropospheric chemistry on hemispheric scales. Two independent estimates of global emissions (Ehhalt, 1999; and TAR/OxComp budget based on the Emission Database for Global Atmospheric Research (EDGAR)) are summarised in Table 4.7a. The OxComp specification of the hydrocarbon mixture for both industrial and biomass-burning emissions is given in Table 4.7b.

One of the NMHC with systematic global measurements is ethane (C_2H_6). Rudolph (1995) have used measurements from five surface stations and many ship and aircraft campaigns during 1980 to 1990 to derive the average seasonal cycle for ethane as a function of latitude. Ehhalt *et al.* (1991) report a trend of +0.8%/yr in the column density above Jungfraujoch, Switzerland for the period 1951 to 1988, but in the following years, the trend turned negative. Mahieu *et al.* (1997) report a trend in C_2H_6 of -2.7 ± 0.3%/yr at Jungfraujoch, Switzerland for 1985 to 1993; Rinsland *et al.* (1998) report a trend of -1.2 ± 0.4%/yr at Kitt Peak, Arizona for 1977 to 1997 and -0.6 ± 0.8%/yr at Lauder, New Zealand for 1993 to 1997. It is expected that anthropogenic emissions of most VOC have risen since pre-industrial times due to increased use of gasoline and other hydrocarbon products. Due to the importance of VOC abundance in determining tropospheric O_3 and OH, systematic measurements and analyses of their budgets will remain important in understanding the chemistry-climate coupling.

There is a serious discrepancy between the isoprene emissions derived by Guenther *et al.* (1995) based on a global scaling of emission from different biomes, about 500 TgC/yr, and those used in OxComp for global chemistry-transport modelling, about 200 TgC/yr. When the larger isoprene fluxes are used in the CTMs, many observational constraints on CO and even isoprene itself are poorly matched. This highlights a key uncertainty in global modelling of highly reactive trace gases: namely, what fraction of primary emissions escapes immediate reaction/removal in the vegetation canopy or immediate boundary layer and participates in the chemistry on the scales represented by global models? For the isoprene budget, there are no measurements of the deposition of reaction products within the canopy. More detail on the scaling of isoprene and monoterpene emissions is provided in Chapter 5. Although isoprene emissions are likely to change in response to evolving chemical and climate environment over the next century, this assessment was unable to include a projection of such changes.

4.2.3.3 Nitrogen oxides (NO_x)

Nitrogen oxides ($NO_x = NO + NO_2$) do not directly affect Earth's radiative balance, but they catalyse tropospheric O_3 formation through a sequence of reactions, e.g.,

$$
\begin{array}{llll}
 & OH + CO + O_2 & \rightarrow & CO_2 + HO_2 \\
 & HO_2 + NO & \rightarrow & NO_2 + OH \\
 & NO_2 + h\nu & \rightarrow & NO + O(^3P) \\
 & O(^3P) + O_2 + M & \rightarrow & O_3 + M \\
 & & & \\
\text{net:} & CO + 2O_2 + h\nu & \rightarrow & CO_2 + O_3
\end{array}
$$

By rapidly converting HO_2 to OH, NO enhances tropospheric OH abundances and thus indirectly reduces the atmospheric burdens of CO, CH_4, and HFCs. Much of recent understanding of the role of NO_x in producing tropospheric O_3 and changing OH abundances is derived from *in situ* measurement campaigns that sample over a wide range of chemical conditions in the upper troposphere or at the surface (see Section 4.2.6 on tropospheric OH). These atmospheric measurements generally support the current photochemical models. There is substantial spatial and temporal variability in the measured abundance of NO_x, which ranges from a few ppt near the surface over the remote tropical Pacific Ocean to >100 ppb in urban regions. The local chemical lifetime of NO_x is always short, but varies widely throughout the troposphere, being 1 day or less in the polluted boundary layer, day or night, and 5 to 10 days in the upper troposphere. As with VOC, it is not possible to derive a global burden or average abundance for NO_x from measurements of atmospheric abundances.

Most tropospheric NO_x are emitted as NO, which photochemically equilibrates with nitrogen dioxide (NO_2) within a few minutes. Significant sources, summarised in Table 4.8, include both surface and *in situ* emissions, and only a small amount is transported down from the stratosphere. NO_x emitted within polluted regions are more rapidly removed than those in remote regions. Emissions directly into the free troposphere have a disproportionately large impact on global greenhouse gases. The major source of NO_x is fossil fuel combustion, with 40% coming from the transportation sector. Benkovitz *et al.* (1996) estimated global emissions at 21 TgN/yr for 1985. The NO_x emissions from fossil fuel use used in model studies here for year 2000 are considerably higher, namely 33 TgN/yr. The large American and European emissions are relatively stable, but emissions from East Asia are increasing by about +4%/yr (Kato and Akimoto, 1992). Other important, but more uncertain surface sources are biomass burning and soil emissions. The soil source recently derived from a bottom-up compilation of over 100 measurements from various ecosystems is 21 TgN/yr (Davidson and Kingerlee, 1997), much higher than earlier estimates. Part of the discrepancy can be explained by the trapping of soil-emitted NO in the vegetation canopy. Inclusion of canopy scavenging reduces the NO_x flux to the free troposphere to 13 TgN/yr, which is still twice the flux estimated by another recent study (Yienger and Levy, 1995). Emissions of NO_x in the free troposphere include NO_x from aircraft (8 to 12 km), ammonia oxidation, and lightning (Lee *et al.*, 1997). Estimates of the lightning NO_x source are quite variable; some recent global estimates are 12 TgN/yr (Price *et al.*, 1997a,b), while other studies recommend 3 to 5 TgN/yr (e.g., Huntrieser *et al.*, 1998; Wang *et al.*, 1998a). Recent studies indicate that the global lightning frequency may be lower than previously estimated (Christian *et al.*, 1999) but that intra-cloud lightning may be much more effective at producing NO (DeCaria *et al.*, 2000). In total, anthropogenic NO_x emissions dominate natural sources, with fossil fuel combustion concentrated in northern industrial regions. However, natural sources may control a larger fraction of the globe. Overall, anthropogenic NO_x emissions are expected to undergo a fundamental shift from the current dominance of the

The TAR column was used in OxComp model calculations for year 2000; fossil fuel includes bio-fuels, but surface sources only; stratospheric source in TAR is upper limit and includes HNO_3; the range of values used in modelling for IPCC aviation assessment (Penner *et al.* 1999) is given.

Northern Hemisphere to a more tropical distribution of emissions. Asian emissions from fossil fuel are expected to drive an overall increase in NO_x emissions in the 21st century (Logan, 1994; Van Aardenne *et al.*, 1999).

The dominant sink of NO_x is atmospheric oxidation of NO_2 by OH to form nitric acid (HNO_3), which then collects on aerosols or dissolves in precipitation and is subsequently scavenged by rainfall. Other pathways for direct NO_x removal occur through canopy scavenging of NO_x and direct, dry deposition of NO_x, HNO_3, and particulate nitrates to the land surface and the ocean. Dry deposition can influence the surface exchanges and can thus alter the release of NO_x and N_2O to the atmosphere. Peroxyacetyl nitrate (PAN), formed by the reaction of $CH_3C(O)O_2$ with NO_2, can transport HO_x and NO_x to remote regions of the atmosphere due to its stability at the cold temperatures of the upper troposphere. In addition tropospheric aerosols provide surfaces on which reactive nitrogen, in the form of NO_3 (nitrate radical) or N_2O_5, is converted to HNO_3 (Dentener and Crutzen, 1993; Jacob, 2000).

Some CTM studies argue against either the large soil source or the large lightning source of NO_x. A climatology of NO_x measurements from aircraft was prepared by Emmons *et al.* (1997) and compared with six chemical transport models. They found that the processes controlling NO_x in the remote troposphere are not well modelled and that, of course, there is a paucity of global NO_x measurements. For short-lived gases like NO_x, resolution of budget discrepancies is even more challenging than for the long-lived species, because the limited atmospheric measurements offer few real constraints on the global budget. However, an additional constraint on the NO_x budget is emerging as the extensive measurements of wet deposition of nitrate over Northern Hemisphere continents are compiled and increasing numbers of surface measurements of dry deposition of HNO_3, NO_2, and particulate nitrate become available, and thus allow a much better estimate of the NO_x sink.

4.2.4 Tropospheric O_3

Tropospheric O_3 is a direct greenhouse gas. The past increase in tropospheric O_3 is estimated to provide the third largest increase in direct radiative forcing since the pre-industrial era. In addition, through its chemical impact on OH, it modifies the lifetimes of other greenhouse gases, such as CH_4. Its budget, however, is much more difficult to derive than that of a long-lived gas for

***Table 4.9:** Estimates of the change in tropospheric ozone since the pre-industrial era from various sources compared with the values recommended in this report.*

Current climatology of tropospheric ozone (Park *et al.*, 1999)**:**

Global mean tropospheric O_3: 34 DU = 370 Tg(O)$_3$ content in the Northern Hemisphere = 36 DU, in the Southern Hemisphere = 32 DU.

SAR recommendation:

"50% of current Northern Hemisphere is anthropogenic" gives pre-industrial global mean content = 25 DU.

Increase = +9 DU

19th & early 20th century observations:[a]

Assume Northern Hemisphere tropospheric ozone has increased uniformly by >30 ppb.

Increase = +10 to +13 DU

Survey of CTM simulated change from pre-industrial:[b]

DU increase	*Model*	*Reference*
9.6	UIO	Berntsen *et al.* (1999)
7.9	GFDL	Haywood *et al.* (1998)
8.9	MOZART-1	Hauglustaine *et al.* (1998)
8.4	NCAR/2D	Kiehl *et al.* (1999)
9.5	GFDL-scaled	Levy *et al.* (1997)
12.0	Harvard/GISS	Mickley *et al.* (1999)
7.2	ECHAM4	Roelofs *et al.* (1997)
8.7	UKMO	Stevenson *et al.* (2000)
8.0	MOGUNTIA	VanDorland *et al.* (1997)

Increase = +7 to +12 DU (model range)

TAR recommendation:

Pre-industrial era global mean tropospheric O_3 has increased from 25 DU to 34 DU.

This increase, +9 DU, has a 67% likely range of 6 to 13 DU.

Increase = +9 DU (+6 to +13 DU)

The troposphere is defined as air with O_3 <150 ppb, see Logan (1999). The Dobson Unit is 1 DU = 2.687 × 10^{16} molecules of O_3 per square centimetre; globally 1 DU = 10.9 Tg(O_3) and 1 ppb of tropospheric O_3 = 0.65 DU. The change in CH_4 alone since pre-industrial conditions would give about +4 DU global increase in tropospheric O_3 alone (see Table 4.11).

[a] Early observations are difficult to interpret and do not provide coverage needed to derive the tropospheric burden of O_3 (see Harris *et al.*, 1997). The change in burden is derived here by shifting tropospheric O_3 uniformly in altitude to give 10 ppb at the surface in Northern Hemisphere mid-latitudes and 20 ppb at surface in Northern Hemisphere tropics (implies 10 DU), or by additionally reducing Southern Hemisphere tropics to 20 ppb and Southern Hemisphere mid-latitudes to 25 ppb at the surface (13 DU).

[b] From a survey of models by Hauglustaine and Solomon and Chapter 4. Except for Kiehl *et al.*, these were all CTMs; they used widely varying assumptions about pre-industrial conditions for CH_4, CO, NO_x, and biomass burning and they did not all report consistent diagnostics.

several reasons. Ozone abundances in the troposphere typically vary from less than 10 ppb over remote tropical oceans up to about 100 ppb in the upper troposphere, and often exceed 100 ppb downwind of polluted metropolitan regions. This variability, reflecting its rapid chemical turnover, makes it impossible to determine the tropospheric burden from the available surface sites, and we must rely on infrequent and sparsely sited profiles from ozone sondes (e.g., Logan, 1999). The total column of ozone is measured from satellites, and these observations have been used to infer the tropospheric ozone column after removing the much larger stratospheric column (e.g., Fishman and Brackett, 1997; Hudson and Thompson, 1998; Ziemke *et al.*, 1998). The current burden of tropospheric O_3 is about 370 Tg(O_3), which is equivalent to a globally averaged column density of 34 DU (Dobson Units, 1 DU = 2.687 × 10^{16} molecules/cm^{-2}) or a mean abundance of about 50 ppb, see Table 4.9.

The sources and sinks of tropospheric ozone are even more difficult to quantify than the burden. Influx of stratospheric air is a source of about 475 Tg(O_3)/yr based on observed correlations with other gases (Murphy and Fahey, 1994; McLinden *et al.*, 2000). The *in situ* photochemical sources are predicted to be many times larger, but are nearly balanced by equally large *in situ* chemical sinks (see discussion on CTM modelling of tropospheric O_3 in Sections 4.4 and 4.5, Table 4.12). Photochemical production of ozone is tied to the abundance of pollutants and thus varies widely over a range of spatial scales, the most important of which (e.g., biomass burning plumes, urban plumes, aircraft corridors, and convective outflows) are not well represented in most global CTMs and cannot be quantified globally with regional models. The dominant photochemical sinks for tropospheric O_3 are the catalytic destruction cycle involving the HO_2 + O_3 reaction and photolytic destruction by pathways involving the reaction of $O(^1D)$, a product of O_3 photodissociation. The other large sink, comparable in magnitude to the stratospheric source, is surface loss mainly to vegetation. Another loss of O_3 is observed under certain conditions in the polar marine boundary layer, notably at the end of Arctic winter. It indicates reactions involving halogen radicals and aerosols (Oum *et al.,* 1998; Dickerson *et al.*, 1999; Impey *et al.*, 1999; Platt and Moortgat, 1999; Prados *et al.*, 1999; Vogt *et al.*, 1999). The contribution of these processes to the global budget is not yet quantified, but is probably small.

Atmospheric measurement campaigns, both at surface sites and with aircraft, have focused on simultaneous observations of the many chemical species involved in tropospheric O_3 production. Primary areas of O_3 production are the mid-latitude industrialised and tropical biomass burning regions. For example, the North Atlantic Regional Experiment (NARE) and the Atmosphere Ocean Chemistry Experiment (AEROCE) showed that the prevailing westerly winds typically carry large quantities of ozone and precursors from the eastern USA over the North Atlantic, reaching Bermuda and beyond (e.g., Dickerson *et al.*, 1995; Penkett *et al.*, 1998; Prados *et al.*, 1999). The Pacific Exploratory Missions (PEM: Hoell *et al.*, 1997, 1999) measured extensive plumes of pollution including ozone and its precursors downwind of eastern Asia. Convective transport of emissions from biomass burning affect the abundance of O_3 in the mid- and upper troposphere (Pickering *et al.,* 1996). Emissions by tropical fires in South America and southern Africa have been identified as the cause of enhanced O_3 over the South Atlantic (Thompson *et al.*, 1996), and the effects of biomass burning were seen in the remote South Pacific in PEM Tropics A (Schultz *et al.*, 1999; Talbot *et al* ., 1999). Due to the widely varying chemical environments, these extensive studies provide a statistical sampling of conditions along with a critical test of the photochemistry in CTM simulations, but they do not provide an integrated budget for tropospheric O_3. An example of such model-and-measurements study is given in the Section 4.2.6 discussion of tropospheric OH.

Recent trends in global tropospheric O_3 are extremely difficult to infer from the available measurements, while trends in the stratosphere are readily identified (Randel *et al.*, 1999; WMO, 1999). With photochemistry producing local lifetimes as short as a few days in the boundary layer, the local measurement of tropospheric O_3 does not reflect the abundance over the surrounding continent, and a surface measurement is not representative of the bulk of the troposphere above. Thus it is not contradictory for decadal trends in different atmospheric regions to be different, e.g., driven by the regional changes in pollutants, particularly NO_x. Ozone sondes offer the best record of O_3 throughout the troposphere, although measurements at many stations are made only weekly (infrequently for a variable gas like O_3). Weekly continuous data since 1970 are available from only nine stations in the latitude range 36°N to 59°N (Logan *et al.*, 1999; WMO, 1999). Different trends are seen at different locations for different periods. Most stations show an increase from 1970 to 1980, but no clear trend from 1980 to 1996. A composite record of the mid-tropospheric O_3 abundance from 1970 to 1996 from the nine stations is taken from the analysis of Logan *et al.* (1999) and presented in Figure 4.8. There is no obvious linear increase in O_3 abundance over this period, although the second half of this record (about 57 ppb) is clearly greater than the first half (about 53 ppb). Of the fourteen stations with records since 1980, only two, one in Japan and one in Europe, had statistically significant increases in mid-tropospheric O_3 between 1980 and 1995. By contrast, the four Canadian stations, all at high latitudes, had significant decreases for the same time period. Surface O_3 measurements from seventeen background stations also show no clear trend, even in the northern mid-latitudes (Oltmans *et al.*, 1998; WMO, 1999). The largest negative trend in surface O_3 was -0.7 ± 0.2%/yr at the South Pole (1975 to 1997), while the largest positive trend was $+1.5 \pm 0.5$%/yr at Zugspitze, Germany (1978 to 1995). This ambiguous record of change over the past two decades may possibly be reconciled with the model predictions (see Section 4.4) of increasing tropospheric O_3 driven regionally by increasing emissions of pollutants: the growth in NO_x emissions is expected to have shifted from North America and Europe to Asia.

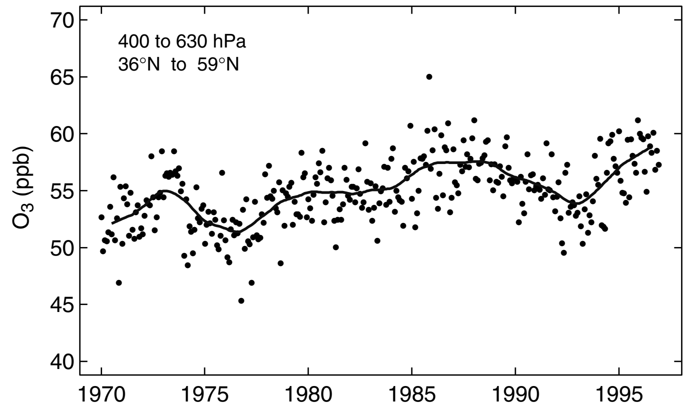

Figure 4.8: Mid-tropospheric O_3 abundance (ppb) in northern mid-latitudes (36°N-59°N) for the years 1970 to 1996. Observations between 630 and 400 hPa are averaged from nine ozone sonde stations (four in North America, three in Europe, two in Japan), following the data analysis of Logan *et al.* (1999). Values are derived from the residuals of the trend fit with the trend added back to allow for discontinuities in the instruments. Monthly data (points) are shown with a smoothed 12-month-running mean (line).

The change in tropospheric O_3 since the pre-industrial era is even more difficult to evaluate on the basis of measurements alone. Since O_3 is reactive, atmospheric abundances cannot be retrieved from ice cores. Recent evaluations of surface measurements in the 19th and early 20th century in Europe (Volz and Kley, 1988; Staehelin *et al.*, 1994, 1998; Harris *et al.*, 1997) indicate much lower O_3 abundances than today, yet the scaling of these data to a tropospheric O_3 burden, even for northern mid-latitudes, is not obvious. In the SAR, these data were used to make a rough estimate that O_3 abundances in the Northern Hemispheric troposphere have doubled since the pre-industrial era. A similar difference, of 10 to 13 DU when globally averaged, is obtained using the climatology given by Park *et al.* (1999) for tropospheric O_3 today and a parallel one with abundances adjusted to match the 19th century measurements in the Northern Hemisphere. CTM calculations predict that current anthropogenic emissions of NO_x, CO, and VOC, as well as the increase in CH_4 should have increased tropospheric O_3 by a similar amount, primarily in the Northern Hemisphere. A recent survey of CTM studies gives global average increases ranging from 8 to 12 DU, although this small range does not adequately represent the uncertainty. These results are summarised in Table 4.9. Based on measurements, analyses, and models, the most likely increase in tropospheric O_3 was 9 DU globally averaged, with a 67% confidence range of 6 to 13 DU. For some of the emissions scenarios considered here, tropospheric O_3 is expected to increase even more in the 21st century as emissions of its precursors – NO_x, CO and VOC – continue to grow (see Section 4.4).

4.2.5 Stratospheric H_2O

Water vapour in the lower stratosphere is a very effective greenhouse gas. Baseline levels of stratospheric H_2O are controlled by the temperature of the tropical tropopause, a parameter that changes with climate (Moyer *et al.*, 1996; Rosenlof *et al.*, 1997; Dessler, 1998; Mote *et al.*, 1998). The oxidation of CH_4 is a source of mid-stratospheric H_2O and currently causes its abundance to increase from about 3 ppm at the tropopause to about 6 ppm in the upper stratosphere. In addition, future direct injections of H_2O from high-flying aircraft may add H_2O to the lower stratosphere (Penner *et al.*, 1999). Oltmans and Hofmann (1995) report statistically significant increases in lower stratospheric H_2O above Boulder, Colorado between 1981 and 1994. The vertical profile and amplitude of these changes do not correspond quantitatively with that expected from the recognised anthropogenic sources (CH_4 oxidation). Analyses of satellite and ground-based measurements (Nedoluha *et al*., 1998; Michelsen *et al*., 2000) find increases in upper stratospheric H_2O from 1985 to 1997, but at rates (>1%/yr) that exceed those from identified anthropogenic sources (i.e., aviation and methane increases) and that obviously could not have been maintained over many decades. In principle such a temporary trend could be caused by a warming tropopause, but a recent analysis indicates instead a cooling tropopause (Simmons *et al*., 1999). It is important to resolve these apparent discrepancies; since, without a physical basis for this recent trend, no recommendation can be made here for projecting changes in lower stratospheric H_2O over the 21st century.

4.2.6 Tropospheric OH and Photochemical Modelling

The hydroxyl radical (OH) is the primary cleansing agent of the lower atmosphere, in particular, it provides the dominant sink for CH_4 and HFCs as well as the pollutants NO_x, CO and VOC. Once formed, tropospheric OH reacts with CH_4 or CO within a second. The local abundance of OH is controlled by the local abundances of NO_x, CO, VOC, CH_4, O_3, and H_2O as well as the intensity of solar UV; and thus it varies greatly with time of day, season, and geographic location.

The primary source of tropospheric OH is a pair of reactions that start with the photodissociation of O_3 by solar UV.

$$O_3 + h\nu \rightarrow O(^1D) + O_2$$
$$O(^1D) + H_2O \rightarrow OH + OH$$

Although in polluted regions and in the upper troposphere, photodissociation of other trace gases such as peroxides, acetone and formaldehyde (Singh *et al.*, 1995; Arnold *et al.*, 1997) may provide the dominant source (e.g., Folkins *et al.*, 1997; Prather and Jacob, 1997; Wennberg *et al.*, 1998; Müller and Brasseur, 1999). OH reacts with many atmospheric trace gases, in most cases as the first and rate-determining step of a reaction chain that leads to more or less complete oxidation of the compound. These chains often lead to formation of an HO_2 radical, which then reacts with O_3 or NO to recycle back to OH. Tropospheric OH is lost through reactions with other radicals, e.g., the reaction with HO_2 to form H_2O or with NO_2 to form HNO_3. In addition to providing the primary loss for CH_4 and other pollutants, HO_x radicals (OH and HO_2) together with NO_x are key catalysts in the production of tropospheric O_3 (see Section 4.2.3.3). The sources and sinks of OH involve most of the fast photochemistry of the troposphere.

Pre-industrial OH is likely to have been different than today, but because of the counteracting effects of lower CO and CH_4 (increasing OH) and reduced NO_x and O_3 (decreasing OH), there is no consensus on the magnitude of this change (e.g., Wang and Jacob, 1998). Trends in the current OH burden appear to be <1%/yr. Separate analyses of the CH_3CCl_3 observations for the period 1978 to 1994 report two different but overlapping trends in global OH: no trend within the uncertainty range (Prinn *et al.*, 1995), and 0.5 ± 0.6%/yr (Krol *et al.*, 1998). Based on the OxComp workshop, the SRES projected emissions would lead to future changes in tropospheric OH that ranging from +5% to −20% (see Section 4.4).

4.2.6.1 Laboratory data and the OH lifetime of greenhouse gases

Laboratory data on the rates of chemical reactions and photodissociation provide a cornerstone for the chemical models used here. Subsequent to the SAR there have been a number of updates to the recommended chemical rate databases of the International Union of Pure and Applied Chemistry (IUPAC 1997a,b, 1999) and the Jet Propulsion Laboratory (JPL) (DeMore *et al.*, 1997; Sander *et al.*, 2000). The CTMs in the OxComp workshop generally used the JPL-1997 database (JPL, 1997) with some updated rates similar to JPL-2000 (JPL, 2000). The most significant changes or additions to the databases include: (i) revision of the low temperature reaction rate coefficients for OH + NO_2 leading to enhancement of HO_x

and NO_x abundances in the lower stratosphere and upper troposphere; (ii) extension of the production of $O(^1D)$ from O_3 photodissociation to longer wavelengths resulting in enhanced OH production in the upper troposphere; and (iii) identification of a new heterogeneous reaction involving hydrolysis of $BrONO_2$ which serves to enhance HO_x and suppress NO_x in the lower stratosphere. These database improvements, along with many other smaller refinements, do not change the overall understanding of atmospheric chemical processes but do impact the modelled tropospheric OH abundances and the magnitude of calculated O_3 changes by as much as 20% under certain conditions.

Reaction rate coefficients used in this chapter to calculate atmospheric lifetimes for gases destroyed by tropospheric OH are from the 1997 and 2000 NASA/JPL evaluations (DeMore *et al.*, 1997; Sander *et al.*, 2000) and from Orkin *et al.* (1999) for HFE-356mff2. These rate coefficients are sensitive to atmospheric temperature and can be ten times faster near the surface than in the upper troposphere. The global mean abundance of OH cannot be directly measured, but a weighted average of the OH sink for certain synthetic trace gases (whose budgets are well established and whose total atmospheric sinks are essentially controlled by OH) can be derived. The ratio of the atmospheric lifetimes against tropospheric OH loss for a gas is scaled to that of CH_3CCl_3 by the inverse ratio of their OH-reaction rate coefficients at an appropriate scaling temperature. A new analysis of the modelled global OH distribution predicts relatively greater abundances at mid-levels in the troposphere (where it is colder) and results in a new scaling temperature for the rate coefficients of 272K (Spivakovsky *et al.*, 2000), instead of 277K (Prather and Spivakovsky, 1990; SAR). The atmospheric lifetimes reported in Table 4.1 use this approach, adopting an "OH lifetime" of 5.7 years for CH_3CCl_3 (Prinn *et al.*, 1995; WMO, 1999). Stratospheric losses for all gases are taken from published values (Ko *et al.*, 1999; WMO, 1999) or calculated as 8% of the tropospheric loss (with a minimum lifetime of 30 years). The only gases in Table 4.1 with surface losses are CH_4 (a soil-sink lifetime of 160 years) and CH_3CCl_3 (an ocean-sink lifetime of 85 years). The lifetime for nitrogen trifluoride (NF_3) is taken from Molina *et al.* (1995). These lifetimes agree with the recent compendium of Naik *et al.* (2000).

Analysis of the CH_3CCl_3 burden and trend (Prinn *et al.*, 1995; Krol *et al.*, 1998; Montzka *et al.*, 2000) has provided a cornerstone of our empirical derivations of the OH lifetimes of most gases. Quantification of the "OH-lifetime" of CH_3CCl_3 has evolved over the past decade. The SAR adopted a value of 5.9 ± 0.7 years in calculating the lifetimes of the greenhouse gases. This range covered the updated analysis of Prinn *et al.* (1995), 5.7 years, which was used in WMO (1999) and adopted for this report. Montzka *et al.* (2000) extend the atmospheric record of CH_3CCl_3 to include the rapid decay over the last five years following cessation of emissions and derive an OH lifetime of 6.3 years. The new information on the CH_3CCl_3 lifetime by Montzka *et al.* (2000) has not been incorporated into this report, but it falls within the ±15% uncertainty for these lifetimes. If the new value of 6.3 years were adopted, then the lifetime of CH_4 would increase to 9.2 yr, and all lifetimes, perturbation lifetimes, and GWPs for gases controlled by tropospheric OH would be about 10% greater.

4.2.6.2 Atmospheric measurements and modelling of photochemistry

Atmospheric measurements provide another cornerstone for the numerical modelling of photochemistry. Over the last five years direct atmospheric measurements of HO_x radicals, made simultaneously with the other key species that control HO_x, have been conducted over a wide range of conditions: the upper troposphere and lower stratosphere (e.g., SPADE, ASHOE/MAESA, STRAT; SUCCESS, SONEX, PEM-TROPICS A & B), the remote Pacific (MLOPEX), and the polluted boundary layer and its outflow (POPCORN, NARE, SOS). These intensive measurement campaigns provide the first thorough tests of tropospheric OH chemistry and production of O_3 for a range of global conditions. As an example here, we present an analysis of the 1997 SONEX (Subsonic assessment program Ozone and Nitrogen oxide EXperiment) aircraft campaign over the North Atlantic that tests one of the chemical models from the OxComp workshop (HGIS).

The 1997 SONEX aircraft campaign over the North Atlantic provided the first airborne measurements of HO_x abundances concurrent with the controlling chemical background: H_2O_2, CH_3OOH, CH_2O, O_3, NO_x, H_2O, acetone and hydrocarbons. These observations allowed a detailed evaluation of our understanding of HO_x chemistry and O_3 production in the upper troposphere. Figure 4.9 (panels 1-3) shows a comparison between SONEX measurements and model calculations (Jaeglé *et al.*, 1999) for OH and HO_2 abundances and the ratio HO_2/OH. At each point the model used the local, simultaneously observed chemical abundances. The cycling between OH and HO_2 takes place on a time-scale of a few seconds and is mainly controlled by reaction of OH with CO producing HO_2, followed by reaction of HO_2 with NO producing OH. This cycle also leads to the production of ozone. As seen in Figure 4.9, the HO_2/OH ratio is reproduced by model calculations to within the combined uncertainties of observations (±20%) and those from propagation of rate coefficient errors in the model (±100%), implying that the photochemical processes driving the cycling between OH and HO_2 appear to be understood (Wennberg *et al.*, 1998; Brune *et al.*, 1999). The absolute abundances of OH and HO_2 are matched by model calculations to within 40% (the reported accuracy of the HO_x observations) and the median model-to-observed ratio for HO_2 is 1.12. The model captures 80% of the observed variance in HO_x, which is driven by the local variations in NO_x and the HO_x sources (Faloona *et al.*, 2000, Jaeglé *et al.*, 2000;). The predominant sources of HO_x during SONEX were reaction of $O(^1D)$ with H_2O and photodissociation of acetone; the role of H_2O_2 and CH_3OOH as HO_x sources was small. This was not necessarily the case in some of the other airborne campaigns, where large differences between measured and modelled OH, up to a factor of 5, were observed in the upper troposphere. In these campaigns the larger measured OH concentrations were tentatively ascribed to enhanced levels of OH precursors, such as H_2O_2, CH_3OOH, or CH_2O, whose concentrations had not been measured.

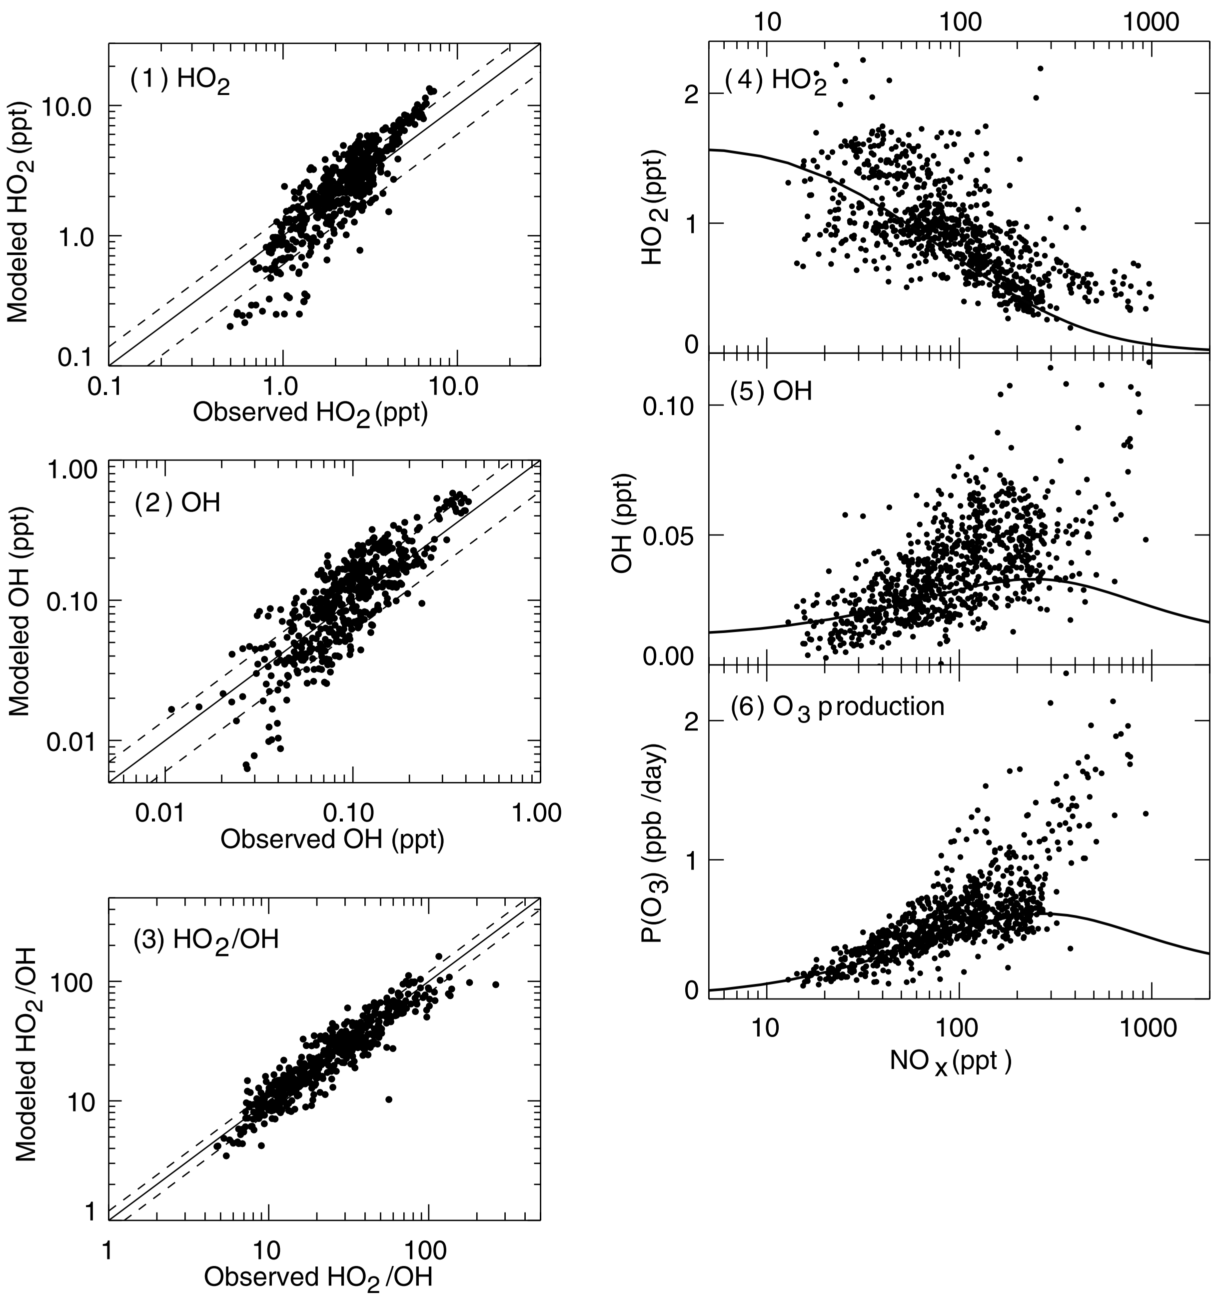

Figure 4.9: (left panel) Observed versus modelled (1) HO_2 abundance (ppt), (2) OH abundance (ppt), and (3) HO_2/OH ratio in the upper troposphere (8 to 12 km altitude) during SONEX. Observations are for cloud-free, daytime conditions. Model calculations are constrained with local observations of the photochemical background (H_2O_2, CH_3OOH, NO, O_3, H_2O, CO, CH_4, ethane, propane, acetone, temperature, pressure, aerosol surface area and actinic flux). The 1:1 line (solid) and instrumental accuracy range (dashed) are shown. Adapted from Brune *et al.* (1999). (right panel) Observed (4) HO_2 abundance (ppt), (5) OH abundance (ppt), and (6) derived O_3 production rate (ppb/day) as a function of the NO_x (NO+NO_2) abundance (ppt). Data taken from SONEX (8 to 12 km altitude, 40° to 60°N latitude) and adapted from Jaeglé *et al.* (1999). All values are 24-hour averages. The lines correspond to model-calculated values as a function of NO_x using the median photochemical background during SONEX rather than the instantaneous values (points).

Tropospheric O_3 production is tightly linked to the abundance of NO_x, and Figure 4.9 (panel 6) shows this production rate (calculated as the rate of the reaction of HO_2 with NO) for each set of observations as function of NO_x during the SONEX mission. Also shown in Figure 4.9 (panels 4-5) are the measured abundances of OH and HO_2 as a function of NO_x. The smooth curve on each panel 4-6 is a model simulation of the expected relationship if the chemical background except for NO_x remained unchanged at the observed median abundances. This curve shows the "expected" behaviour of tropospheric chemistry when only NO_x is increased: OH increases with NO_x abundances up to 300 ppt because HO_2 is shifted into OH; it decreases with increasing NO_x at higher NO_x abundances because the OH reaction with NO_2 forming HNO_3 becomes the dominant sink for HO_x radicals.

Production of O_3 is expected to follow a similar pattern with rates suppressed at NO_x abundances greater than 300 ppt under these atmospheric conditions (e.g., Ehhalt, 1998). These SONEX observations indicate, however, that both OH abundance and O_3 production may continue to increase with NO_x concentrations up to 1,000 ppt because the high NO_x abundances were often associated with convection and lightning events and occurred simultaneously with high HO_x sources. By segregating observations according to HO_x source strengths, Jaeglé *et al.* (1999) identified the approach to NO_x-saturated conditions predicted by the chemical models when HO_x sources remain constant. A NO_x-saturated environment was clearly found for the POPCORN (Photo-Oxidant formation by Plant emitted Compounds and OH Radicals in north-eastern Germany) boundary layer measurements in Germany (Rohrer *et al.*, 1998; Ehhalt and Rohrer, 2000). The impact of NO_x-saturated conditions on the production of O_3 is large in the boundary layer, where much of the NO_x is removed within a day, but may be less important in the upper troposphere, where the local lifetime of NO_x is several days and the elevated abundances of NO_x are likely to be transported and diluted to below saturation levels. This effective reduction of the NO_x-saturation effect due to 3-D atmospheric mixing is seen in the CTM modelling of aviation NO_x emissions where a linear increase in tropospheric O_3 is found, even with large NO_x emissions in the upper troposphere (Isaksen and Jackman, 1999).

4.3 Projections of Future Emissions

The IPCC SRES (Nakićenović *et al.*, 2000) developed 40 future scenarios that are characterised by distinctly different levels of population, economic, and technological development. Six of these scenarios were identified as illustrative scenarios and these were used for the analyses presented in this chapter. The SRES scenarios define only the changes in anthropogenic emissions and not the concurrent changes in natural emissions due either to direct human activities such as land-use change or to the indirect impacts of climate change. The annual anthropogenic emissions for all greenhouse gases, NO_x, CO, VOC and SO_2 (sulphur dioxide) are given in the SRES for the preliminary marker scenarios (Nakićenović *et al.*, 2000, Appendix VI) and the final marker/illustrative scenarios (Nakićenović *et al.*, 2000, Appendix VII). Much of these data is also tabulated in Appendix II to this report. There are insufficient data in the published SRES (Nakićenović *et al.*, 2000) to break down the individual contributions to HFCs, PFCs, and SF_6, but these emissions were supplied by Lead Authors of the SRES (available at sres.ciesin.org) and are also reproduced in this Appendix. The geographic distribution of emissions of the short-lived compounds – NO_x, CO, VOC, and SO_2 – is an important factor in their greenhouse forcing, and the preliminary gridded emissions were likewise supplied by the SRES Lead Authors (Tom Kram and Steven Smith, December 1998) and used in the OxComp model studies. A synopsis of the regional shift in CO and NO_x emissions projected by 2100 is given in Tables 4.6 and 4.8.

This chapter evaluates the SRES emissions from year 2000 to year 2100 in terms of their impact on the abundances of non-CO_2 greenhouse gases. A new feature of this report, i.e., use of NO_x, CO and VOC emissions to project changes in tropospheric O_3 and OH, represents a significant advance over the level-of-science in the SAR. The original four preliminary marker scenarios (December 1998) are included here because they have been used in preliminary model studies for the TAR and are designated A1p, A2p, B1p, B2p. In January 1999, these emissions were converted into greenhouse gas abundances using the level-of-science and methodology in the SAR, and the radiative forcings from these greenhouse gas abundances were used in this report for some climate model simulations.

The recently approved six marker/illustrative scenarios (March 2000) are also evaluated and are designated A1B-AIM, A1T-MESSAGE, A1FI-MiniCAM, A2-ASF, B1-IMAGE, B2-MESSAGE (hereafter abbreviated as A1B, A1T, A1FI, A2, B1, B2). For comparison with the previous assessment, we also evaluate the IPCC emissions scenario IS92a used in the SAR; for the full range of IS92 scenarios, see the SAR. An agreed-upon property of all SRES scenarios is that there is no intervention to reduce greenhouse gases; but, in contrast, regional controls on SO_2 emissions across the illustrative SRES scenarios lead to emissions in the last two decades of the century that are well below those of 1990 levels. There appear to be few controls on NO_x, CO and VOC emissions across all scenarios; however, the large increases in surface O_3 abundances implied by these results may be inconsistent with the SRES storylines that underpin the emissions scenarios. As understanding of the relationship between emissions and tropospheric O_3 abundances improves, particularly on regional scales, more consistent emissions scenarios can be developed. The SRES scenarios project substantial emissions of HFC-134a as in IS92a, but only half as much HFC-125, and no emissions of HFC-152a. The SRES emissions scenarios do include a much larger suite of HFCs plus SF_6 and PFCs, which are not included in IS92a. The emissions of greenhouse gases under the Montreal Protocol and its Amendments (CFCs, HCFCs, halons) have been evaluated in WMO (Madronich and Velders, 1999). This report adopts the single WMO baseline Montreal Protocol Scenario A1 (no relation to SRES A1) for emissions and concentrations of these gases, while the SRES adopted a similar WMO Scenario A3 (maximum production); however, the differences between scenarios in terms of climate forcing is inconsequential. The resulting abundances of greenhouse gases are given in Appendix II and discussed in Section 4.4.5.

4.3.1 The Adjusted/Augmented IPCC/SRES Emission Scenarios

Among the four SRES preliminary marker scenarios, A2p has overall the highest emissions. For model simulations of future atmospheric chemistry in the OxComp workshop, we needed to focus on a single test case and chose scenario A2p in the year 2100 since it represents the largest increase in emissions of CH_4, CO, NO_x, and VOC. Once the response of O_3 and OH to these extreme emissions is understood, other scenarios and intermediate years can be interpolated with some confidence.

Y2000

For the OxComp workshop, we adopt Y2000 emissions that include both natural and anthropogenic sources. The OxComp Y2000 anthropogenic emissions are roughly consistent with, but different in detail from, the anthropogenic emissions provided by SRES. These adjustments were necessary to be consistent with current budgets, to include natural sources as discussed previously, and to provide more detailed information on source categories, including temporal and spatial distribution of emissions that are not specified by SRES. Emissions of NO_x, CO and VOC for the year 2000 are based on GEIA(Global Emissions Inventory Activity)/EDGAR emissions for 1990 (Graedel *et al.*, 1993; Olivier *et al.*, 1999) projected to year 2000. Tropospheric abundances of long-lived gases such as CH_4 were fixed from recent observations. The difference between SRES and OxComp Y2000 emissions are nominally within the range of uncertainty for these quantities. The OxComp Y2000 simulations provide a "current" atmosphere to compare with observations.

Y2100(A2p)
Since the OxComp Y2000 emissions differ somewhat from the A2p emissions for the year 2000, we define Y2100(A2p) emissions by the sum of our adjusted Y2000 emissions plus the difference between the SRES-A2p emissions for the years 2100 and 2000. Thus our absolute increase in emissions matches that of SRES-A2p. In these Y2100(A2p) simulations, natural emissions were not changed.

4.3.2 Shifting Regional Emissions of NO_x CO, and VOC in 2100

A shift of the growth of anthropogenic emissions of NO_x, CO and VOC, such as that from North America and Europe to Southern and Eastern Asia over the past decades, is changing the geographic pattern of emissions, which in turn will change the distribution of the O_3 increases in the troposphere predicted for the year 2100. In contrast, for long-lived greenhouse gases, shifting the location of emissions has little impact. We use the SRES emission maps, to take into account such changes in emissions patterns. For Y2000 and Y2100(A2p) the emissions of CO and NO_x, broken down by continents, are given in Tables 4.6 and 4.8, respectively. In terms of assessing future changes in tropospheric OH and O_3, it is essential to have a coherent model for emissions scenarios that consistently projects the spatial patterns of the emissions along with the accompanying changes in urbanisation and land use.

4.3.3 Projections of Natural Emissions in 2100

SRES scenarios do not consider the changes in natural emissions and sinks of reactive gases that are induced by alterations in land use and agriculture or land-cover characteristics. (Land-use change statistics, however, are reported, and these could, in principle, be used to estimate such changes.) In some sense these altered emissions must be considered as anthropogenic changes. Examples of such changes may be increased NO_x, N_2O and NH_3 emissions from natural waters and ecosystems near agricultural areas with intensified use of N-fertiliser. A change of land cover, such as deforestation, may lead to reduced isoprene emissions but to increases in soil emissions of NO_x. At present we can only point out the lack of projecting these parallel changes in once natural emissions as an uncertainty in this assessment.

4.4 Projections of Atmospheric Composition for the 21st Century

4.4.1 Introduction

Calculating the abundances of chemically reactive greenhouse gases in response to projected emissions requires models that can predict how the lifetimes of these gases are changed by an evolving atmospheric chemistry. This assessment focuses on predicting changes in the oxidative state of the troposphere, specifically O_3 (a greenhouse gas) and OH (the sink for many greenhouse gases). Many research groups have studied and predicted changes in global tropospheric chemistry, and we seek to establish a consensus in these predictions, using a standardised set of scenarios in a workshop organised for this report. The projection of stratospheric O_3 recovery in the 21st century – also a factor in radiative forcing and the oxidative state of the atmosphere – is reviewed extensively in WMO (Hofmann and Pyle, 1999), and no new evaluation is made here. The only stratospheric change included implicitly is the N_2O feedback on its lifetime. Overall, these projections of atmospheric composition for the 21st century include the most extensive set of trace gas emissions for IPCC assessments to date: greenhouse gases (N_2O, CH_4, HFCs, PFCs, SF_6) plus pollutants (NO_x, CO, VOC).

4.4.2 The OxComp Workshop

In the SAR, the chapter on atmospheric chemistry included two modelling studies: PhotoComp (comparison of ozone photochemistry in box models) and Delta-CH_4 (methane feedbacks in 2-D and 3-D tropospheric chemistry models). These model studies established standard model tests for participation in IPCC. They resulted in a consensus regarding the CH_4 feedback and identified the importance (and lack of uniform treatment) of NMHC chemistry on tropospheric O_3 production. This synthesis allowed for the SAR to use the CH_4-lifetime feedback and a simple estimate of tropospheric O_3 increase due solely to CH_4. The SAR noted that individual CTMs had calculated an impact of changing NO_x and CO emissions on global OH and CH_4 abundances, but that a consensus on predicting future changes in O_3 and OH did not exist.

Since 1995, considerable research has gone into the development and validation of tropospheric CTMs. The IPCC Special Report on Aviation and the Global Atmosphere (Derwent and Friedl, 1999) used a wide range of global CTMs to predict the enhancement of tropospheric O_3 due to aircraft NO_x emissions. The results were surprisingly robust, not only for the hemispheric mean O_3 increase, but also for the increase in global mean OH reported as a decrease in the CH_4 lifetime. The current state-of-modelling in global tropospheric chemistry has advanced since PhotoComp and Delta-CH_4 in the SAR and now includes as standard a three-dimensional synoptic meteorology and treatment of non-methane hydrocarbon chemistry. A survey of

recent CTM-based publications on the tropospheric O_3 budget, collected for this report, is discussed in Section 4.5.

This assessment, building on these developments, organised a workshop to compare CTM results for a few, well-constrained atmospheric simulations. An open invitation, sent out in March 1999 to research groups involved in 3-D global tropospheric chemistry modelling, invited participation in this report's assessment of change in tropospheric oxidative state through a model intercomparison and workshop (OxComp). This workshop is an IPCC-focused follow-on to the Global Integration and Modelling (GIM) study (Kanakidou *et al.*, 1999). The infrastructure for OxComp (ftp site, database, graphics, and scientific support) was provided by the University of Oslo group, and the workshop meeting in July 1999 was hosted by the Max Planck Institute for Meteorology (MPI) Hamburg. Participating models are described by publications in peer-reviewed literature as summarised in Table 4.10; all include 3-D global tropospheric chemistry including NMHC; and assessment results are based on models returning a sufficient number of OxComp cases. The two goals of OxComp are (i) to build a consensus on current modelling capability to predict changes in tropospheric OH and O_3 and (ii) to develop a useful parametrization to calculate the greenhouse gases (including tropospheric O_3 but not CO_2) using the IPCC emissions scenarios.

4.4.3 Testing CTM Simulation of the Current (Y2000) Atmosphere

The OxComp workshop defined a series of atmospheres and emission scenarios. These included Y2000, a new reference atmosphere meant to represent year 2000 that provides a baseline from which all changes in greenhouse gases were calculated. For Y2000, abundances of long-lived gases were prescribed by 1998 measurements (Table 4.1a), and emissions of short-lived pollutants, NO_x, CO and VOC, were based primarily on projections to the year 2000 of GEIA/EDGAR emissions for 1990 (Olivier *et al.*, 1998, 1999), see Section 4.3.1. Stratospheric O_3 was calculated in some models and prescribed by current observation in others. The predicted atmospheric quantities in all these simulations are therefore short-lived tropospheric gases: O_3, CO, NO_x, VOC, OH and other radicals. Following the GIM model study (Kanakidou *et al.*, 1999), we use atmospheric measurement of O_3 and CO to test the model simulations of the current atmosphere. The Y2000 atmosphere was chosen because of the need for an IPCC baseline, and it does not try to match conditions over the l980s and 1990s from which the measurements come. Although the observed trends in tropospheric O_3 and CO are not particularly large over this period and thus justify the present approach, a more thorough comparison of model results and measurements would need to use the regional distribution of the pollutant emissions for the observation period.

The seasonal cycle of O_3 in the free troposphere (700, 500, and 300 hPa) has been observed over the past decade from more than thirty ozone sonde stations (Logan, 1999). These measurements are compared with the OxComp Y2000 simulations for Resolute (75°N), Hohenpeissenberg (48°N), Boulder (40°N), Tateno (36°N), and Hilo (20°N) in Figure 4.10. Surface measurements from Cape Grim (40°S), representative of the marine boundary layer in southern mid-latitudes, are also compared with the models in Figure 4.10. With the exception of a few outliers, the model simulations are within ±30% of observed tropospheric O_3 abundance, and they generally show a maximum in spring to early summer as observed, although they often miss the month of maximum O_3. At 300 hPa the large springtime variation at many stations is due to the influence of stratospheric air that is approximately simulated at Resolute, but, usually overestimated at the other stations. The CTM simulations in the tropics (Hilo) at 700 to 500 hPa show much greater spread and hence generally worse agreement with observations. The mean concentration of surface O_3 observed at Cape Grim is well matched by most models, but the seasonality is underestimated.

Observed CO abundances are compared with the Y2000 model simulations in Figure 4.11 for surface sites at various altitudes and latitudes: Cape Grim (CGA, 94 m), Tae Ahn (KOR,

Model results from OxComp workshop; all changes (DU for O_3 and % for OH) are relative to the year Y2000. Tropospheric mean OH is weighted by CH_4 loss rate. Mean O_3 changes (all positive) are derived from the standard reporting grid on which the CTMs interpolated their results. See Table 4.10 for the model key. The different cases include (A) a 10% increase in CH_4 to 1,920 ppb and (B) a full 2100 simulation following SRES draft marker scenario A2 (based on February 1999 calculations for preliminary work of this report). Case C drops the NO_x emissions back to Y2000 values; and case D drops NO_x, VOC, and CH_4 likewise.

Adopted CH_4 abundances and pollutant emissions from Y2000 to Y2100 are:

Y2000: CH_4=1,745 ppb, e–NO_x=32.5 TgN/yr, e–CO=1,050 Tg/yr, e–VOC=150 Tg/yr.

Y2100: CH_4=4,300 ppb, e–NO_x=110.0 TgN/yr, e–CO=2,500 Tg/yr, e–VOC=350 Tg/yr.

[a] N.B. Unfortunately, after the government review it was discovered that the method of integrating O_3 changes on the reporting grid was not well defined and resulted in some unintentional errors in the values reported above. Thus, the values here include in effect the O_3 increases predicted/expected in the lower stratosphere in addition to the troposphere. In terms of climate change, use of these values may not be unreasonable since O_3 changes in the lower stratosphere do contribute to radiative forcing. Nevertheless, the troposphere-only changes are about 25 to 33% less than the values above.

$$\delta(\text{tropospheric } O_3) = +5.0\times\delta\ln(CH_4) + 0.125\times\delta(e-NO_x) + 0.0011\times\delta(e-CO) + 0.0033\times\delta(e-VOC) \text{ in DU.}$$

[b] TAR adopts the weighted average for cases A to D as shown, where the weighting includes factors about model formulation and comparison with observations. A linear interpolation is derived from these results and used in the scenarios:

$$\delta\ln(\text{tropospheric OH}) = -0.32\times\delta\ln(CH_4) + 0.0042\times\delta(e-NO_x) - 1.05e-4\times\delta(e-CO) - 3.15e-4\times\delta(e-VOC),$$

$$\delta(\text{effective } O_3) = +6.7\times\delta\ln(CH_4) + 0.17\times\delta(e-NO_x) + 0.0014\times\delta(e-CO) + 0.0042\times\delta(e-VOC) \text{ in DU.}$$

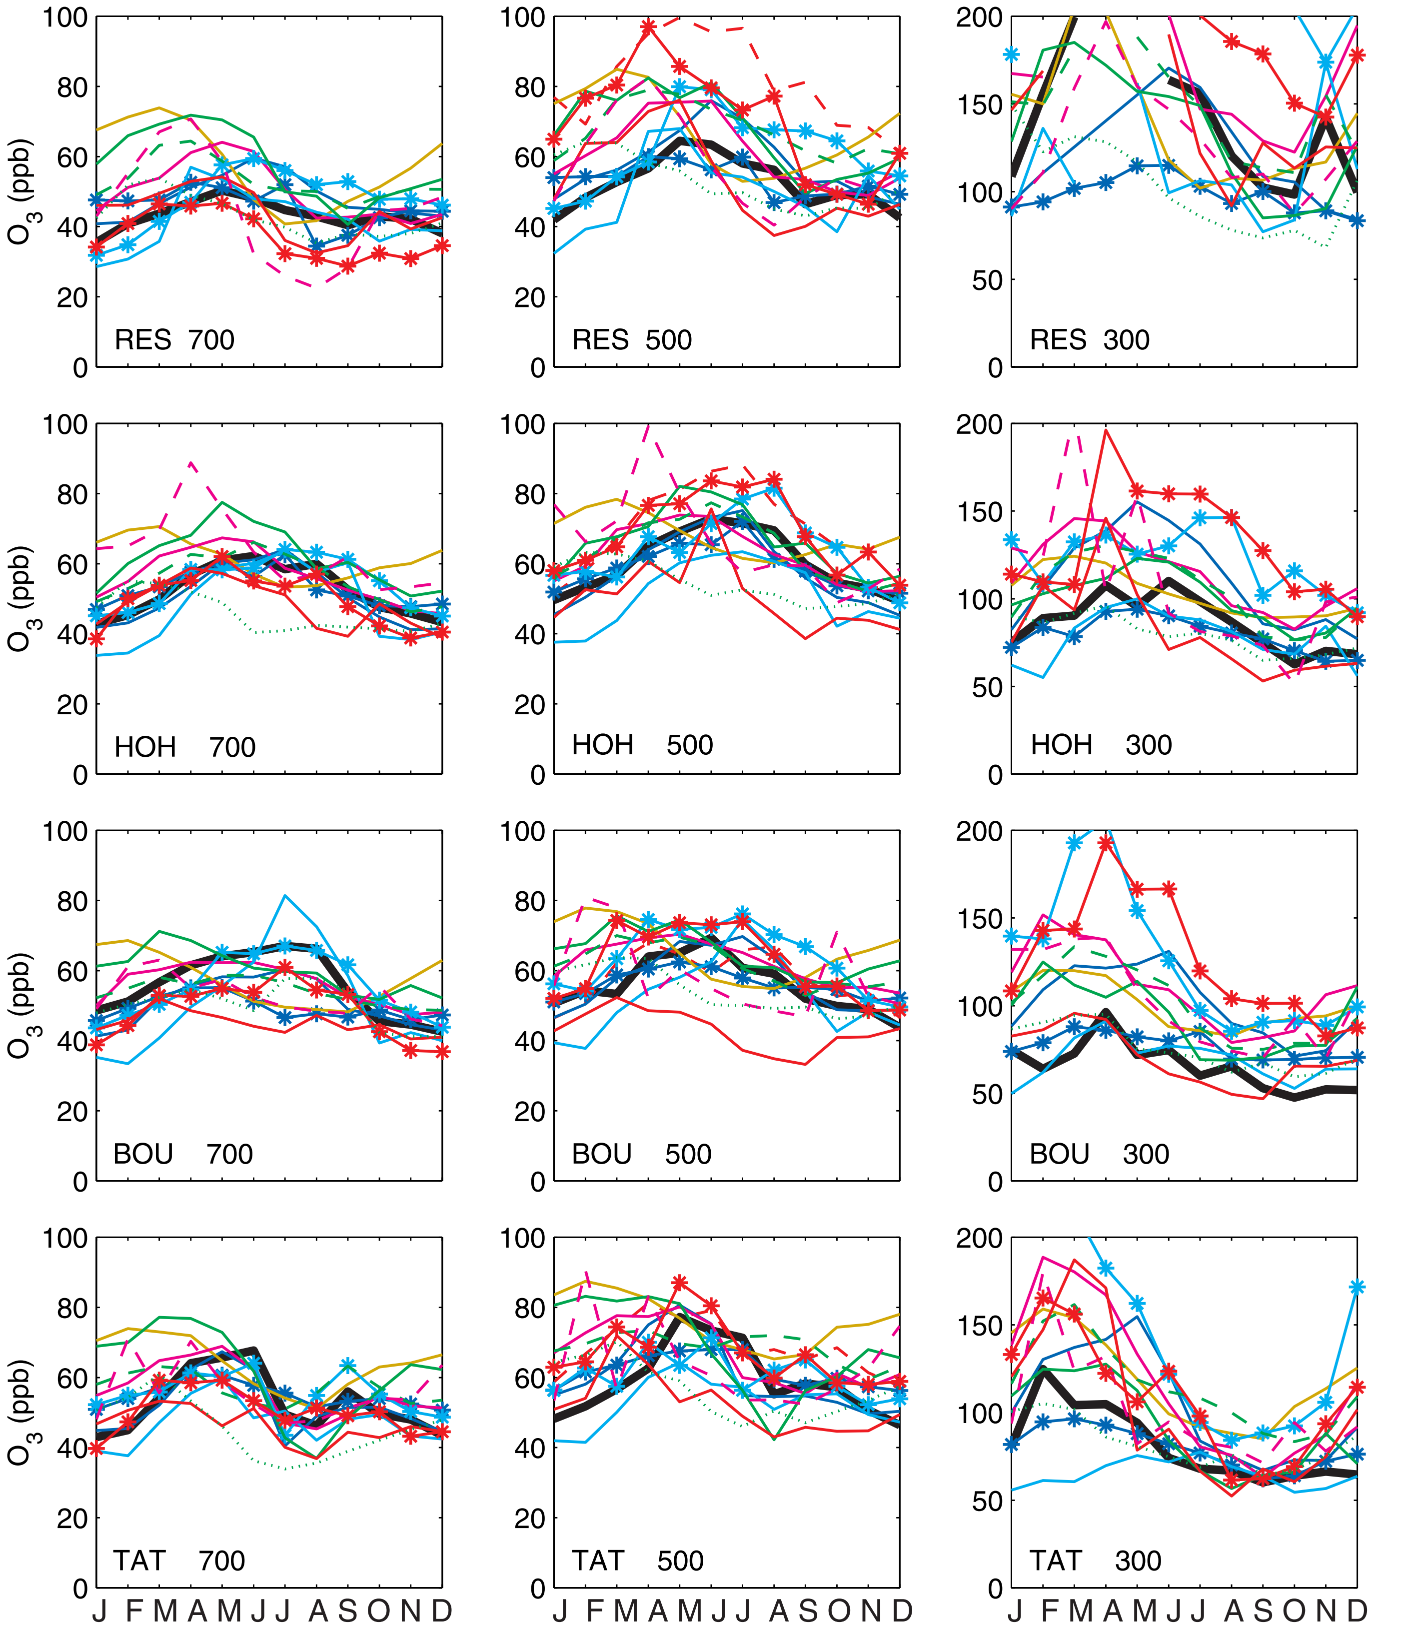

Figure 4.10: Observed monthly mean O_3 abundance (ppb) from sondes at 700 hPa (left column), 500 hPa (centre) and 300 hPa (right) from a sample of stations (thick black line) compared with Y2000 model simulations from OxComp (thin coloured lines, see model key in legend and Table 4.10). The sonde stations include RESolute (75°N, 95°W), HOHenpeissenberg (48ºN, 11°E), BOUlder (40°N, 105°W), TATeno (36°N, 140°E), and HILo (20°N, 155°W). Surface monthly O_3 observations (thick black line) at Cape Grim Observatory (CGA, 40°S, 144°E, 94 m above mean sea level) are also compared with the models. (Continues opposite.)

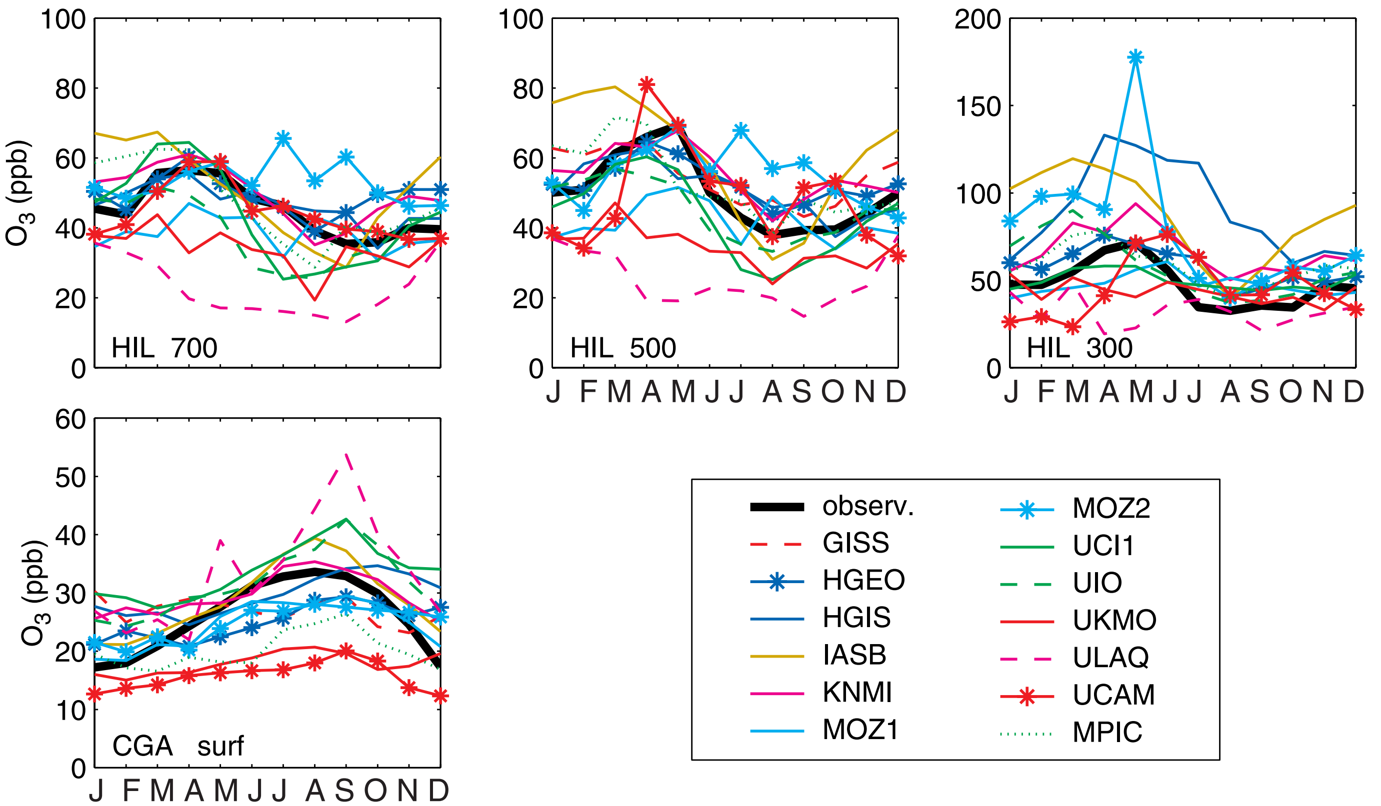

20 m), Mauna Loa (MLH, 3397 m), Alert (ALT, 210 m), and Niwot Ridge (NWR, 3475 m). The Alert abundances are well matched by most but not all models. Niwot Ridge and Mauna Loa are reasonably well modelled except for the February to March maximum. At Tae Ahn, the models miss the deep minimum in late summer, but do predict the much larger abundances downwind of Asian sources. At Cape Grim the seasonal cycle is matched, but the CO abundance is uniformly overestimated (30 to 50%) by all the models, probably indicating an error in Southern Hemisphere emissions of CO.

Overall, this comparison with CO and O_3 observations shows good simulations by the OxComp models of the global scale chemical features of the current troposphere as evidenced by CO and O_3; however, the critical NO_x chemistry emphasises variability on much smaller scales, such as biomass burning plumes and lightning storms, that are not well represented by the global models. With this large variability and small scales, the database of NO_x measurements needed to provide a test for the global models, equivalent to CO and O_3, would need to be much larger.

The current NO_x database (e.g., Emmons *et al.*, 1997; Thakur *et al.*, 1999) does not provide critical tests of CTM treatment of these sub-grid scales.

4.4.4 Model Simulations of Perturbed and Y2100 Atmospheres

The OxComp workshop also defined a series of perturbations to the Y2000 atmosphere for which the models reported the monthly averaged 3-D distribution of O_3 abundances and the budget for CH_4, specifically the loss due to reaction with tropospheric OH. From these diagnostics, the research group at Oslo calculated the change in global mean tropospheric O_3 (DU) and in OH (%) relative to Y2000, as shown in Table 4.11. For each model at every month, the "troposphere" was defined as where O_3 abundances were less than 150 ppb in the Y2000 simulation, a reasonably conservative diagnostic of the tropopause (see Logan, 1999). Because O_3 is more effective as a greenhouse gas when it lies above the surface boundary layer (SAR; Hansen *et al.*, 1997a; Prather and Sausen, 1999; Chapter 6 of this report), the model study diagnosed the O_3 change occurring in the 0 to 2 km layers of the model. This amount is typically 20 to 25% of the total change and is consistent across models and types of perturbations here.

Case A, a +10% increase in CH_4 abundance for Y2000, had consistent results across reporting models that differed little from the SAR's Delta-CH_4 model study. The adopted values for this report are −3% change in OH and +0.64 DU increase in O_3, as listed under the "TAR" row in Table 4.11.

The Y2100 atmosphere in OxComp mimics the increases in pollutant emissions in SRES A2p scenario from year 2000 to year 2100 with the year 2100 abundance of CH_4, 4,300 ppb, calculated with the SAR technology and named here A2x. (See discussion in section 4.4.5; for the SAR, only the CH_4-OH feedback is included.) The long-lived gases CO_2 and N_2O have no impact on these tropospheric chemistry calculations as specified.

Cases B-C-D are a sequence of three Y2100 atmospheres based on A2x: Case B is the full Y2100-A2x scenario; Case C is the same Y2100-A2x scenario but with unchanged (Y2000) NO_x

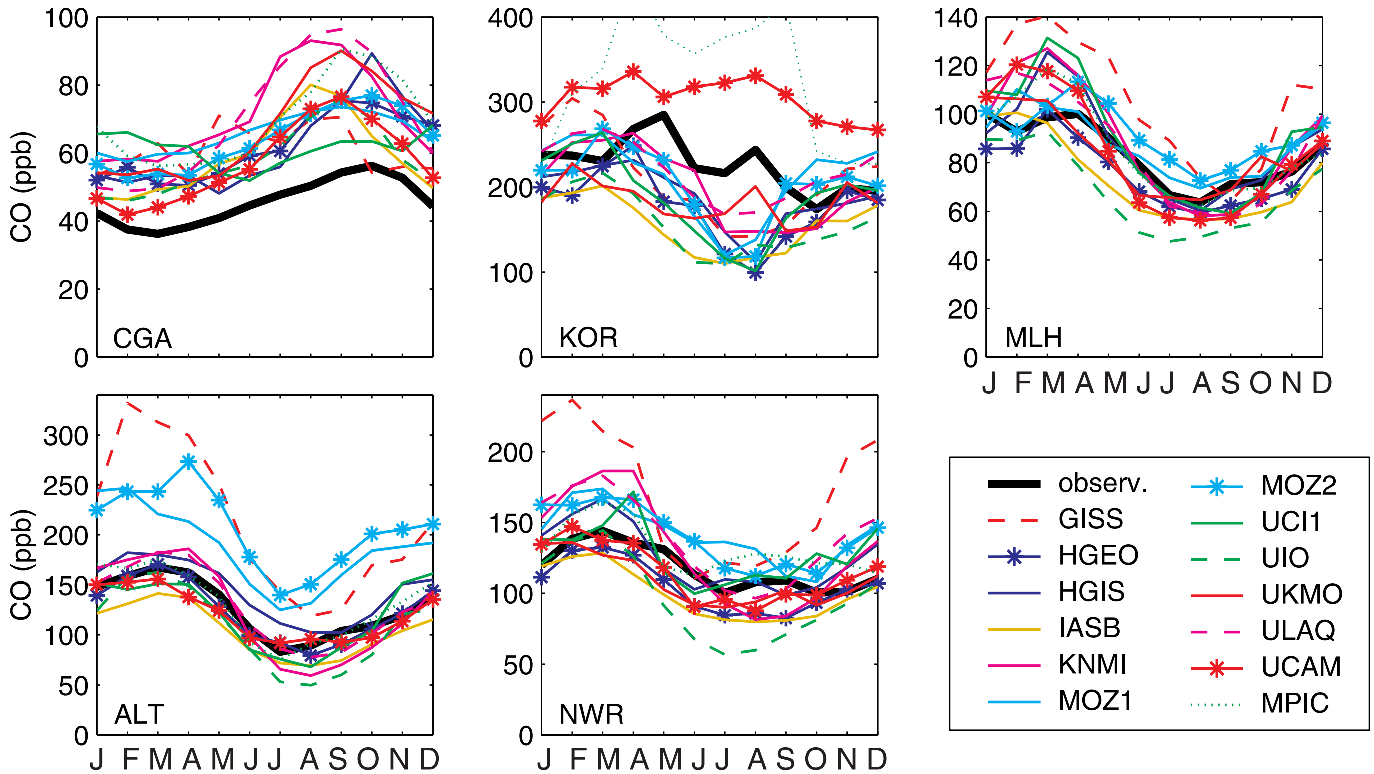

Figure 4.11: Observed seasonal surface CO abundance (ppb, thick black lines) at Cape Grim (CGA: 40°S, 144°E, 94 m above mean sea level), Tae Ahn (KOR: 36°N, 126°E, 20 m), Mauna Loa (MLH: 19°N, 155°W, 3397 m), Alert (ALT: 82°N, 62°W, 210 m), and Niwot Ridge (NWR: 40°N, 105°W, 3475 m) are compared with the OxComp model simulations from Y2000, see Figure 4.10.

emissions; and Case D is the same but with NO_x, VOC and CH_4 unchanged since Y2000 (i.e., only CO emissions change). Case B (Y2100-A2x) results are available from most OxComp participants. All models predict a decrease in OH, but with a wide range from –6 to –25%, and here we adopt a decrease of –16%. Given the different distributions of the O_3 increase from the OxComp models (Figures 4.12-13), the increases in globally integrated O_3 were remarkably consistent, ranging from +16.6 to +26.5 DU, and we adopt +22 DU. Without the increase in NO_x emissions (Case C) the O_3 increase drops substantially, ranging from +4.6 to +14.5 DU; and the OH decrease is large, –37 to –43%. With only CO emissions (Case D) the O_3 increase is smallest in all models, +0.4 to +5.9 DU.

This report adopts a weighted, rounded average of the changes in OH and O_3 for cases A-D as shown in the bold rows in Table 4.11. The weighting includes factors about model formulation and comparison with observations. This sequence of calculations (Y2000 plus Cases A-B-C-D) allows us to define a simple linear relationship for the absolute change in tropospheric O_3 and the relative change in OH as a function of the CH_4 abundance and the emission rates for NO_x, for CO, and for VOC. These two relationships are given in Table 4.11. Since the change in CH_4 abundance and other pollutant emissions for Y2100-A2x are among the largest in the SRES scenarios, we believe that interpolation of the O_3 and OH changes for different emission scenarios and years introduces little additional uncertainty.

The possibility that future emissions of CH_4 and CO overwhelm the oxidative capacity of the troposphere is tested (Case E, see Table 4.3 footnote &) with a +10% increase in CH_4 on top of Y2100-A2x (Case B). Even at 4,300 ppb CH_4, the decrease in OH calculated by two CTMs is only slightly larger than in Case A, and thus, at least for SRES A2p, the CH_4-feedback factor does not become as large as in the runaway case (Prather, 1996). This report assumes that the CH_4 feedback remains constant over the next century; however, equivalent studies for the low-NO_x future scenarios are not assessed.

The apparent agreement on predicting the single global, annual mean tropospheric O_3 increase, e.g., Case B in Table 4.11, belies the large differences as to where this increase occurs and what is its peak magnitude. The spatial distributions of the tropospheric O_3 increases in July for Case B are shown in Figure 4.12 (latitude by altitude zonal average abundance, ppb) and Figure 4.13 (latitude by longitude column density, DU) for nine CTMs. The largest increase in abundance occurs near the tropopause at 40°N latitude; yet some models concentrate this increase in the tropics and others push it to high latitudes. In terms of column density, models generally predict large increases along the southern edge of Asia from Arabia to eastern China; although the increases in tropical, biomass-burning regions varies widely from model to model.

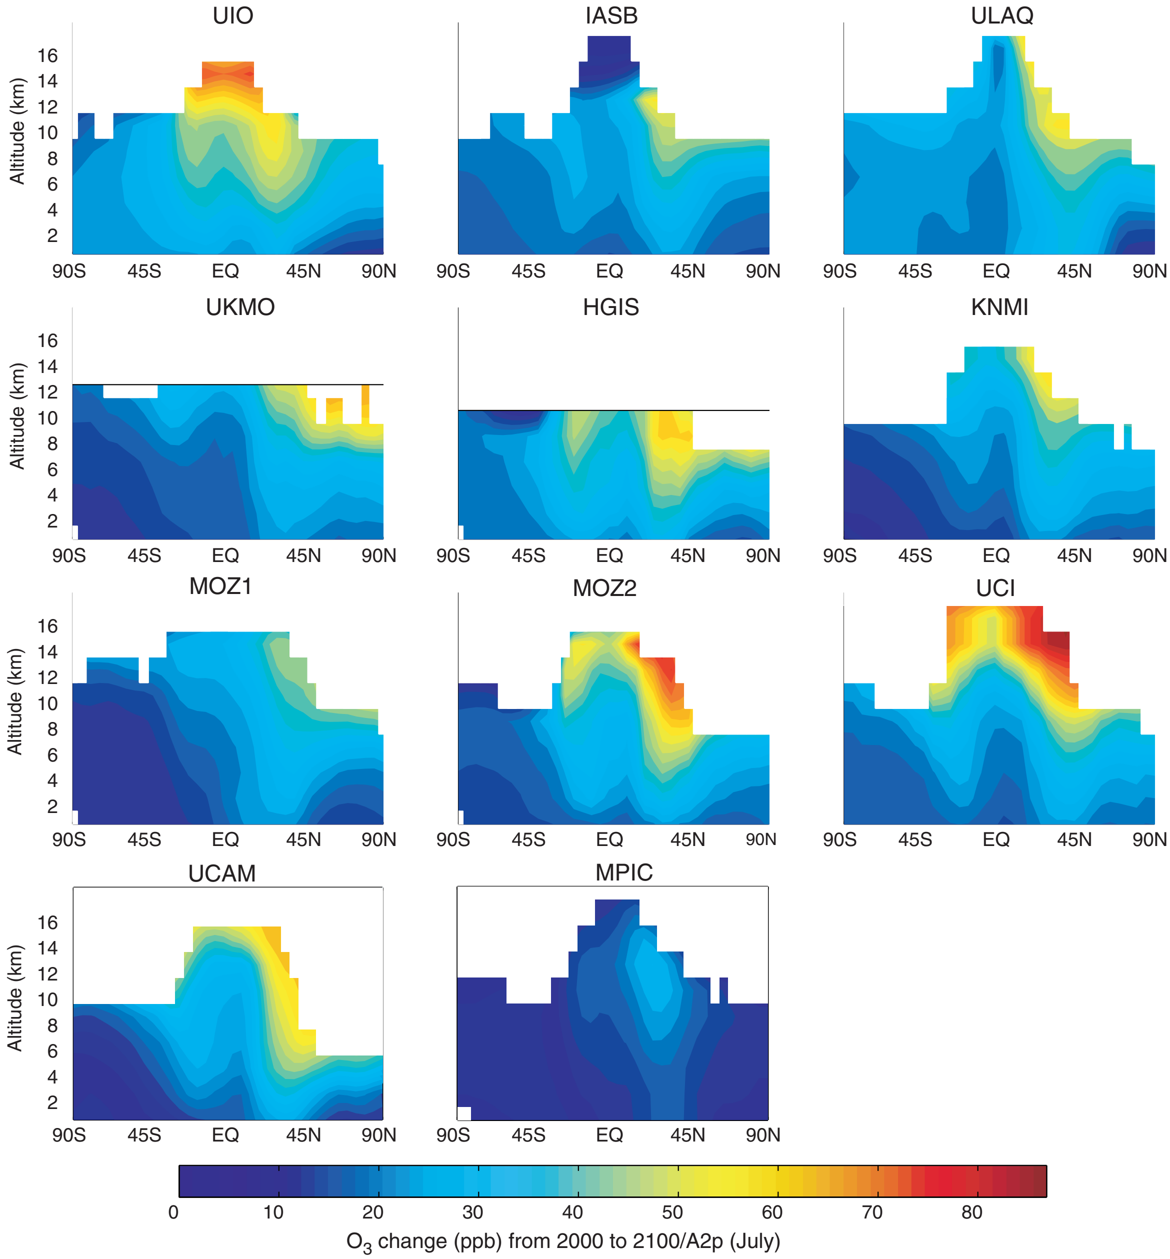

Figure 4.12: July zonal mean increase in tropospheric O_3 (ppb) as a function of latitude and altitude from Y2000 to Y2100 adopting SRES A2p projections for CH_4, CO, VOC, and NO_x. Results are shown for a sample of the chemistry-transport models (CTM) participating in IPCC OxComp workshop. Increases range from 0 to more than 80 ppb. Changes in the stratosphere (defined as $O_3 > 150$ ppb in that model's Y2000 simulation) are masked off, as are also regions in the upper troposphere for some CTMs (UKMO, HGIS) where O_3 is not explicitly calculated. See Table 4.10 for participating models.

This similarity in the total, but difference in the location, of the predicted O_3 increases is noted in Isaksen and Jackman (1999) and is probably due to the different transport formulations of the models as documented in previous CTM intercomparisons (Jacob *et al.*, 1997). Possibly, the agreement on the average O_3 increase may reflect a more uniform production of O_3 molecules as a function of NO_x emissions and CH_4 abundance across all models. Nevertheless, the large model range in the predicted patterns of O_3 perturbations leads to a larger uncertainty in climate impact than is indicated by Table 4.11.

The projected increases in tropospheric O_3 under SRES A2 and A1FI will have serious consequences on the air quality of most of the Northern Hemisphere by year 2100. Taking only the global numbers from Figure 4.14, the mean abundance of tropospheric O_3 will increase from about 52 ppb (typical mid-tropospheric abundances) to about 84 ppb in year 2100. Similar increases of about +30 ppb are seen near the surface at 40°N on a zonal average in Figure 4.12. Such increases will raise the "background" levels of O_3 in the northern mid-latitudes to close to the current clean-air standard.

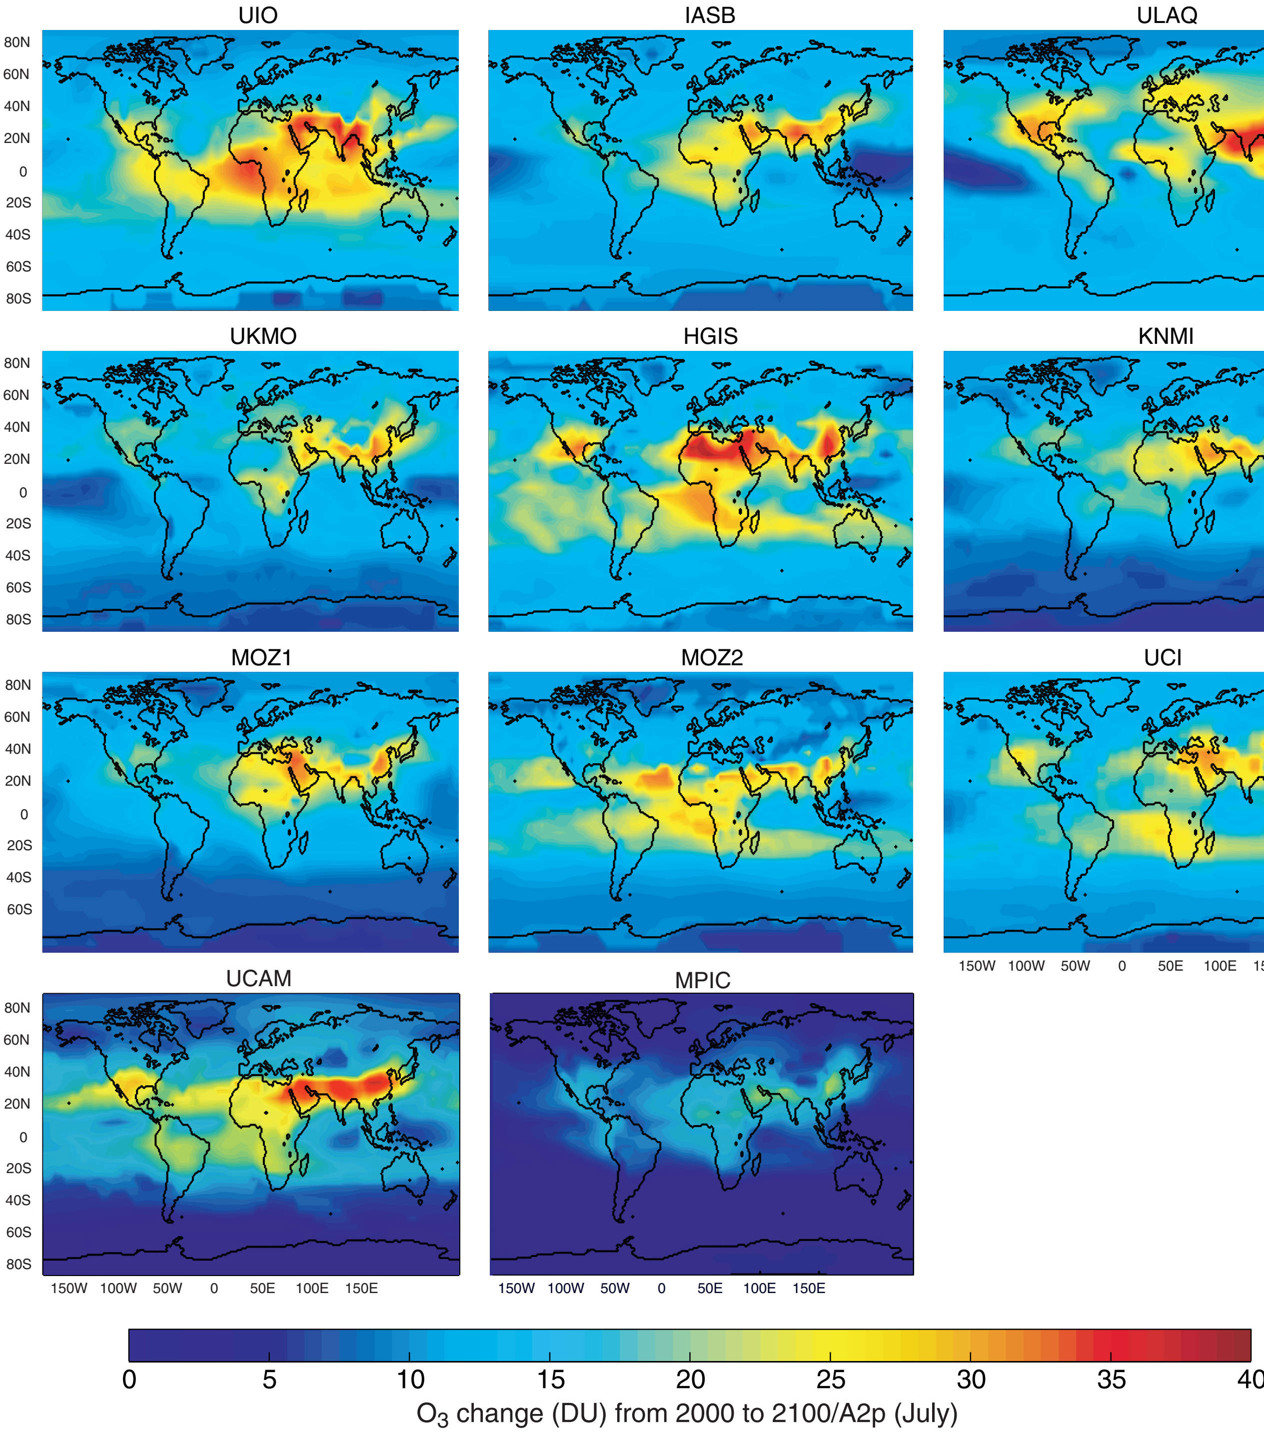

Figure 4.13: July column increase in tropospheric O_3 (DU) as a function of latitude and longitude from Y2000 to Y2100 adopting SRES A2p projections for CH_4, CO, VOC, and NO_x is shown for some OxComp simulations. See Figure 4.12.

4.4.5 Atmospheric Composition for the IPCC Scenarios to 2100

Mean tropospheric abundances of greenhouse gases and other chemical changes in the atmosphere are calculated by this chapter for years 2000 to 2100 from the SRES scenarios for anthropogenic emissions of CH_4, N_2O, HFCs, PFCs, SF_6, NO_x, CO, and VOC (corresponding emissions of CO_2 and aerosol precursors are not used). The emissions from the six SRES marker/illustrative scenarios (A1B, A1T, A1FI, A2, B1, B2) are tabulated in Appendix II, as are the resulting greenhouse gas abundances, including CO_2 and aerosol burdens. Chlorine- and bromine-containing greenhouse gases are not calculated here, and we adopt the single baseline scenario from the WMO assessment (Montreal Protocol Scenario A1 of Madronich and Velders, 1999), which is reproduced in Appendix II. Also given in Appendix II are the parallel data for the SRES preliminary marker scenarios (A1p, A2p, B1p, B2p) and, in many cases, the SAR scenario IS92a as a comparison with the previous assessment.

Greenhouse gas abundances are calculated using a methodology similar to the SAR: (1) The troposphere is treated as a single box with a fill-factor for each gas that relates the burden to the tropospheric mean abundance (e.g., Tg/ppb). (2) The atmospheric lifetime for each gas is recalculated each year based on conditions at the beginning of the year and the formulae in Table 4.11. (Changes in tropospheric OH are used to scale the lifetimes of CH_4 and HFCs, and the abundance of N_2O is used to calculate its new lifetime.) (3) The abundance of a gas is integrated exactly over the year assuming that emissions remain constant for 12 months. (4) Abundances are annual means, reported at the beginning of each year (e.g., year 2100 = 1 January 2100).

In the SAR, the only OH feedback considered was that of CH_4 on its own lifetime. For this report, we calculate the change in tropospheric OH due to CH_4 abundance as well as the immediate emissions of NO_x, CO and VOC. Likewise, the increase in tropospheric O_3 projected in the SAR considered only increases in CH_4; whereas now it includes the emissions of NO_x, CO and VOC. Thus the difference between IS92a in the SAR and in this report is similar to that noted by Kheshgi *et al.* (1999). Also, the feedback of N_2O on its lifetime is included here for the first time and shows up as reduction of 14 ppb by year 2100 in this report's IS92a scenario as compared to the SAR.

The 21st century abundances of CH_4, N_2O, tropospheric O_3, HFC-134a, CF_4, and SF_6 for the SRES scenarios are shown in Figure 4.14. Historical data are plotted before year 2000; and the SRES projections, thereafter to year 2100. CH_4 continues to rise in B2, A1FI, and A2 (like IS92a), with abundances reaching 2,970 to 3,730 ppb, in order. For A1B and A1T, CH_4 peaks in mid-century at about 2,500 ppb and then falls. For B1, CH_4 levels off and eventually falls to 1980-levels by year 2100. N_2O continues to rise in all scenarios, reflecting in part its long lifetime, and abundances by the end of the century range from 350 to 460 ppb. Most scenarios lead to increases in tropospheric O_3, with scenarios A1FI and A2 projecting the maximum tropospheric O_3 burdens of 55 DU by year 2100. This increase of about 60% from today is more than twice the change from pre-industrial to present. Scenario B1 is alone in projecting an overall decline in tropospheric O_3 over most of the century: the drop to 30 DU is about halfway back to pre-industrial values. HFC-134a, the HFC with the largest projected abundance, is expected to reach about 900 ppt by year 2100 for all scenarios except B1. Likewise by 2100, the abundance of CF_4 rises to 340 to 400 ppt in all scenarios except B1. The projected increase in SF_6 is much smaller in absolute abundance, reaching about 60 ppt in scenarios A1 and A2. For the major non-CO_2 greenhouse gases, the SRES A2 and A1FI increases are similar to, but slightly larger than, those of IS92a. The SRES mix of lesser greenhouse gases (HFCs, PFCs, SF_6) and their abundances are increased substantially relative to IS92a. The summed radiative forcings from these gases plus CO_2 and aerosols are given in Chapter 6.

The chemistry of the troposphere is changing notably in these scenarios, and this is illustrated in Figure 4.14 with the lifetime (LT) of CH_4 and the change in mean tropospheric OH relative to year 2000. In all scenarios except B1, OH decreases 10% or more by the end of the century, pushing the lifetime of CH_4 up from 8.4 years, to 9.2 to 10.0 years. While increasing emissions of NO_x in most of these scenarios increases O_3 and would tend to increase OH (see notes to Table 4.11), the increase in CH_4 abundance and the greater CO emissions appear to dominate, driving OH down. In such an atmosphere, emissions of CH_4 and HFCs persist longer with greater greenhouse impact. In contrast the B1 atmosphere is more readily able to oxidise these compounds and reduce their impact.

4.4.6 Gaps in These Projections – the Need for Coupled Models

There are some obvious gaps in these projections where processes influencing the greenhouse gas abundances have been omitted. One involves coupling of tropospheric chemistry with the stratosphere. For one, we did not include the recovery of stratospheric ozone expected over the next century. The slow recovery of stratospheric ozone depletion from the halogens will lead to an increase in the flux of ozone into the troposphere and also to reduced solar UV in the troposphere, effectively reversing over the next century what has occurred over the past two decades. A more important impact on the Y2100 stratosphere, however, is the response to increases in CH_4 and N_2O projected by most scenarios (see Hofmann and Pyle, 1999), which in terms of coupled stratosphere-troposphere chemistry models could be evaluated in only one of the OxComp models (ULAQ, Université degli studi dell' Aguila) and is not included here.

Another major gap in these projections is the lack of global models coupling the atmospheric changes with biogeochemical models. There have been studies that tackled individual parts of the problem, e.g., deposition of reactive N (Holland *et al.*, 1997), crop damage from O_3 (Chameides *et al.*, 1994). Integrated assessment studies have coupled N_2O and CH_4 emission models with lower dimension or parametrized climate and chemistry models (e.g., Alcamo, 1994; Holmes and Ellis, 1999; Prinn *et al.*, 1999). However, the inherent local nature of this coupling, along with the possible feedbacks through, for example NO and VOC emissions, point to the need for coupled 3-D global chemistry and ecosystem models in these assessments.

Finally, there is an obvious need to couple the physical changes in the climate system (water vapour, temperature, winds, convection) with the global chemical models. This has been partially accomplished for some cases that are highlighted here (Section 4.5.2), but like other gaps presents a major challenge for the next assessment.

4.4.7 Sensitivity Analysis for Individual Sectors

In order to assess the overall impact of changing industry or agriculture, it would be necessary to combine all emissions from a specific sector or sub-sector as has been done with the IPCC assessment of aviation (Penner *et al.*, 1999). Further, the impact on natural emissions and land-use change (e.g., albedo, aerosols) would also need to be included. Such a sector analysis would cut across Chapters 3, 4, 5 and 6 of this report (e.g., as in Prather and

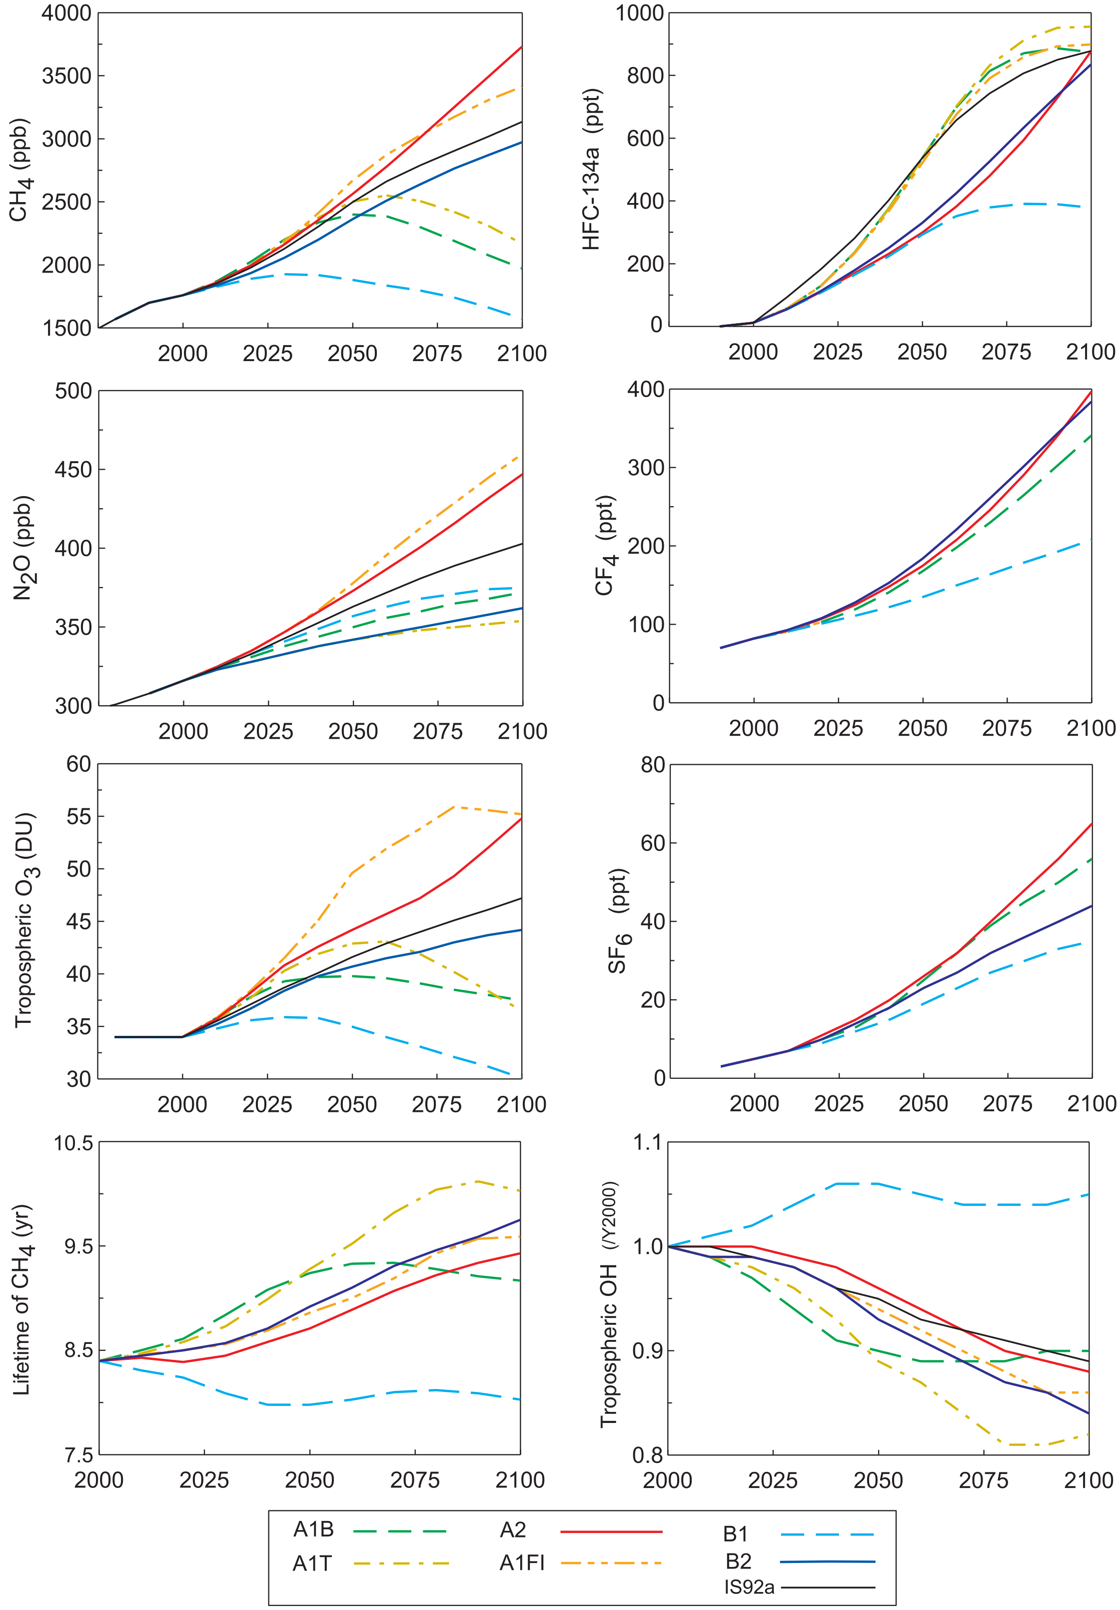

Figure 4.14: Atmospheric composition and properties predicted using the six SRES Marker-Illustrative scenarios for anthropogenic emissions: A1B (green dashed line), A1T (yellow dash-dotted), A1FI (orange dash-dot-dotted), A2 (red solid), B1 (cyan dashed), B2 (solid dark blue). Abundances prior to year 2000 are taken from observations, and the IS92a scenario computed with current methodology is shown for reference (thin black line). Results are shown for CH_4 (ppb), N_2O (ppb), tropospheric O_3 (DU), HFC-134a (ppt), CF_4 (ppt), SF_6 (ppt), the lifetime of CH_4 (yr), and the global annual mean abundance of tropospheric OH (scaled to year 2000 value). All SRES A1-type scenarios have the same emissions for HFCs, PFCs, and SF_6 (appearing a A1B), but the HFC-134a abundances vary because the tropospheric OH values differ affecting its lifetime. The IS92a scenario did not include emissions of PFCs and SF_6. For details, see chapter text and tables in Appendix II.

Sausen, 1999). Such an analysis cannot be done for the SRES emissions scenarios, which lack a breakdown by sector and also lack numbers for the changes in the land area of agriculture or urbanisation.

4.5 Open Questions

Many processes involving atmospheric chemistry, and the coupling of atmospheric chemistry with other elements of global change, have been proposed in the scientific literature. These are generally based on sound physical and chemical principles, but unfortunately, there is no consensus on their quantitative role in atmospheric chemistry on a global scale (e.g., the effects of clouds on tropospheric ozone: Lelieveld and Crutzen (1990) vs. Liang and Jacob (1997)), on the magnitude of possible compensating effects (e.g., net settling of HNO_3 on cloud particles: Lawrence and Crutzen (1999) vs. full cloud-scale dynamics), or even on how to implement them or whether these are already effectively included in many of the model calculations. While many of these processes may be important, there is inadequate information or consensus to make a quantitative evaluation in this assessment. This assessment is not a review, and so this section presents only a few examples of recent publications studying feedbacks or chemical processes, which are not included, but which are potentially important in this assessment.

4.5.1 Chemical Processes Important on the Global Scale

4.5.1.1 Missing chemistry, representation of small scales, and changing emission patterns

Analyses and observations (see Section 4.2.6) continue to test and improve the chemistry and transport used in the global CTMs. In terms of the chemistry, recent studies have looked, for example, at the representation of NMHC chemistry (Houweling *et al.* 1998; Wang *et al.* 1998b), the role of halogens in the O_3 budget of the remote marine troposphere, and the acetone source of upper tropospheric OH (see Sections 4.2.4 and 4.2.6). Most of these improvements in understanding will eventually become adopted as standard in the global CTMs, but at this stage, for example, the role of tropospheric halogen chemistry on the Y2100 predictions has not been evaluated in the CTMs.

Convection, as well as urban pollution and biomass burning plumes, occur on horizontal scales not resolved in global CTMs. These sub-grid features appear to be important in calculating OH abundances and O_3 production for biomass burning emissions (Pickering *et al.*, 1996; Folkins *et al.*, 1997), for the remote upper troposphere (Jaeglé *et al.*, 1997; Prather and Jacob, 1997; Wennberg *et al.*, 1998), and in urban plumes (e.g., Sillman *et al.*, 1990). Convection is represented in all CTMs here (e.g., Collins *et al.*, 1999; Müller and Brasseur, 1999) but in quite different ways, and it still involves parametrization of processes occurring on a sub-grid scale. A substantial element of the differences in CTM simulations appears to lie with the different representations of convection and boundary layer transport, particularly for the short-lived gases such as NO_x.

A change in the geographic emission pattern of the pollutants (NO_x, CO and VOC) can by itself alter tropospheric O_3 and OH abundances and in turn the abundances of CH_4 and HFCs. In one study of regional NO_x emissions and control strategy, Fuglestvedt *et al.* (1999) find that upper tropospheric O_3 is most sensitive to NO_x reductions in Southeast Asia and Australia and least to those in Scandinavia. Understanding trends in CO requires knowledge not only of the *in situ* chemistry of CO (e.g., Granier *et al.*, 1996; Kanakidou and Crutzen, 1999), but also of how local pollution control has altered the global pattern of emissions (e.g., Hallock-Waters *et al.*, 1999). These shifts have been included to some extent in the SRES emissions for year 2100 used here; however, the projected change in emission patterns have not been formally evaluated within the atmospheric chemistry community in terms of uncertainty in the Y2100 global atmosphere.

4.5.1.2 Aerosol interactions with tropospheric O_3 and OH

Over the past decade of assessments, stratospheric O_3 chemistry has been closely linked with aerosols, and global models in the recent WMO assessments have included some treatment of the stratospheric sulphate layer and polar stratospheric clouds. In the troposphere, studies have identified mechanisms that couple gas-phase and aerosol chemistry (Jacob, 2000). Many aerosols are photochemically formed from trace gases, and at rates that depend on the oxidative state of the atmosphere. Such processes are often included in global aerosol models (see Chapter 5). The feedback of the aerosols on the trace gas chemistry includes a wide range of processes: conversion of NO_x to nitrates, removal of HO_x, altering the UV flux and hence photodissociation rates (e.g., Dickerson *et al.*, 1997; Jacobson, 1998), and catalysing more exotic reactions leading to release of NO_x or halogen radicals. These processes are highly sensitive to the properties of the aerosol and the local chemical environment, and their importance on a global scale is not yet established. Only the first example above of aerosol chemistry is generally included in many of the CTMs represented here; however, the surface area of wet aerosols (that converts NO_x to HNO_3 via the intermediate species NO_3 and N_2O_5) is usually specified and not interactively calculated. More laboratory and field research is needed to define the processes so that implementation in global scale models can evaluate their quantitative impact on these calculations of greenhouse gases.

4.5.1.3 Stratosphere-troposphere coupling

The observed depletion of stratospheric ozone over the past three decades, which can be attributed in large part but not in total to the rise in stratospheric chlorine levels, has been reviewed extensively in WMO (1999). This depletion has lead to increases in tropospheric UV and hence forces tropospheric OH abundances upward (Bekki *et al.*, 1994). The total effect of such a change is not simple and involves the coupled stratosphere-troposphere chemical system; for example, ozone depletion may also have reduced the influx of O_3 from the stratosphere, which would reduce tropospheric O_3 (Karlsdottir *et al.*, 2000) and tend to reverse the OH trend. Such chemical feedbacks are reviewed as “climate-chemistry” feedbacks in WMO 1999 (Granier and Shine, 1999). There is insufficient understanding or quantitative consensus on these effects to be included in this assessment. While chlorine-driven O_3 depletion becomes much less of an issue in the latter half of the 21st century, the projected increases in CO_2, CH_4, and N_2O may cause even larger changes in stratospheric O_3. The lack of coupled CTMs that include stratospheric changes adds uncertainty to these projections.

4.5.1.4 Uncertainties in the tropospheric O_3 budget

An updated survey of global tropospheric CTM studies since the SAR focuses on the tropospheric O_3 budget and is reported in Table 4.12. In this case authors were asked for diagnostics that did not always appear in publication. The modelled tropospheric O_3 abundances generally agree with observations; in most cases the net budgets are in balance; and yet the individual components vary greatly. For example, the stratospheric source ranges from 400 to 1,400 Tg/yr, while the surface sink is only slightly more constrained, 500 to 1,200 Tg/yr. If absolute production is diagnosed as the reactions of HO_2 and other peroxy radicals with NO, then the globally integrated production is calculated to be very large, 2,300 to 4,300 Tg/yr and is matched by an equally large sink (see Sections 4.2.3.3 and 4.2.6). The differences between the flux from the stratosphere and the destruction at the surface is balanced by the net *in situ* photochemical production. In this survey, the net production varies widely, from −800 to +500 Tg/yr, indicating that in some CTMs the troposphere is a large chemical source and in others a large sink. Nevertheless, the large differences in the stratospheric source are apparently the driving force behind whether a model calculates a chemical source or sink of tropospheric O_3. Individual CTM studies of the relative roles of stratospheric influx versus tropospheric chemistry in determining the tropospheric O_3 abundance (e.g., Roelofs and Lelieveld, 1997; Wang *et al.*, 1998a; Yienger *et al.*, 1999) will not represent a consensus until all CTMs develop a more accurate representation of the stratospheric source consistent with observations (Murphy and Fahey, 1994).

4.5.2 Impacts of Physical Climate Change on Atmospheric Chemistry

As global warming increases in the next century, the first-order atmospheric changes that impact tropospheric chemistry are the anticipated rise in temperature and water vapour. For example, an early 2-D model study (Fuglestvedt *et al.*, 1995) reports that tropospheric O_3 decreases by about 10% in response to a warmer, more humid climate projected for year 2050 as compared to an atmosphere with current temperature and H_2O. A recent study based on NCAR (National Center for Atmospheric Research) CCM (Community Climate Model) projected year 2050 changes in tropospheric temperature and H_2O (Brasseur *et al.*, 1998a) finds a global mean 7% increase in the OH abundance and a 5% decrease in tropospheric O_3, again relative to the same calculation with the current physical climate.

A 3-D tropospheric chemistry model has been coupled to the Hadley Centre Atmosphere-Ocean General Circulation Model (AOGCM) and experiments performed using the SRES preliminary marker A2p emissions (i) as annual snapshots (Stevenson *et al.*, 2000) and (ii) as a 110-year, fully coupled experiment (Johnson *et al.*, 1999) for the period 1990 to 2100. By 2100, the experiments with coupled climate change have increases in CH_4 which are only about three-quarters those of the simulation without climate change and increases in Northern Hemisphere mid-latitude O_3 which are reduced by half. The two major climate-chemistry feedback mechanisms identified in these and previous studies were (1) the change of chemical reaction rates with the average 3°C increase in tropospheric temperatures and (2) the enhanced photochemical destruction of tropospheric O_3 with the approximately 20% increase in water vapour. The role of changes in the circulation and convection appeared to play a lesser role but have not been fully evaluated. These studies clearly point out the importance of including the climate-chemistry feedbacks, but are just the beginning of the research that is needed for adequate assessment.

Thunderstorms, and their associated lightning, are a component of the physical climate system that provides a direct source of a key chemical species, NO_x. The magnitude and distribution of this lightning NO_x source controls the magnitude of the anthropogenic perturbations, e.g., that of aviation NO_x emissions on upper tropospheric O_3 (Berntsen and Isaksen, 1999). In spite of thorough investigations of the vertical distribution of lightning NO_x (Huntrieser *et al.*, 1998; Pickering *et al.* 1998), uncertainty in the source strength of lightning NO_x cannot be easily derived from observations (Thakur *et al.*, 1999; Thompson *et al.*, 1999). The link of lightning with deep convection (Price and Rind, 1992) opens up the possibility that this source of NO_x would vary with climate change, however, no quantitative evaluation can yet be made.

4.5.3 Feedbacks through Natural Emissions

Natural emissions of N_2O and CH_4 are currently the dominant contributors to their respective atmospheric burdens, with terrestrial emissions greatest in the tropics. Emissions of both of these gases are clearly driven by changes in physical climate as seen in the ice-core record (Figure 4.1e). Soil N_2O emissions are sensitive to temperature and soil moisture and changes in rates of carbon and nitrogen cycling (Prinn *et al.*, 1999). Similarly, methane emissions from wetlands are sensitive to the extent of inundation, temperature rise, and changes in rates of carbon and nitrogen cycling. Natural emissions of the pollutants NO_x, CO, and VOC play an important role in production of tropospheric O_3 and the abundance of OH; and these emissions are subject to similar forcings by both the physical and chemical climates. Terrestrial and aquatic ecosystems in turn respond to near-surface pollution (O_3, NO_2, acidic gases and aerosols) and to inadvertent fertilisation through deposition of reactive nitrogen (often emitted from the biosphere as NO or NH_3). This response can take the form of die back, reduced growth, or changed species composition competition that may alter trace gas surface exchange and ecosystem health and function. The coupling of this feedback system – between build-up of greenhouse gases, human-induced climate change, ecosystem responses, trace gas exchange at the surface, and back to atmospheric composition – has not been evaluated in this assessment. The variety and complexity of these feedbacks relating to ecosystems, beyond simple increases with rising temperatures and changing precipitation, argues strongly for the full interactive coupling of biogeochemical models of trace gas emissions with chemistry and climate models.

Table 4.12: *Tropospheric ozone budgets for circa 1990 conditions from a sample of global 3-D CTMs since the SAR.*

STE = stratosphere-troposphere exchange (net flux from stratosphere) (Tg/yr).
Prod & Loss = *in situ* tropospheric chemical terms, P–L = net. (Tg/yr).
SURF = surface deposition (Tg/yr). Burden = total content (Tg, 34DU = 372Tg).
Budgets should balance exactly (STE+P–L=SURF), but may not due to roundoff.
[a] Results using CH_4-only chemistry without NMHC.
[b] Budget/burden calculated from surface to 250 hPa (missing part of upper troposphere).

4.6 Overall Impact of Global Atmospheric Chemistry Change

The projected growth in emissions of greenhouse gases and other pollutants in the IPCC SRES scenarios for the 21st century is expected to increase the atmospheric burden of non-CO_2 greenhouse gases substantially and contribute a sizable fraction to the overall increase in radiative forcing of the climate. These changes in atmospheric composition may, however, degrade the global environment in ways beyond climate change.

The impact of metropolitan pollution, specifically O_3 and CO, on the background air of the Atlantic and Pacific Oceans has been highlighted by many studies over the past decade. These have ranged from observations of anthropogenic pollution reaching across the Northern Hemisphere (e.g., Parrish *et al.*, 1993; Jaffe *et al.*, 1999) to analyses of rapidly increasing emissions of pollutants (NO_x, CO, VOC) in, for example, East Asia (Kato and Akimoto 1992; Elliott *et al.*, 1997). CTM studies have tried to quantify some of these projections for the near term: Berntsen *et al.* (1999) predict notable increases in CO and O_3 coming into the north-west USA from a doubling of current Asian emissions; Jacob *et al.* (1999) calculate that monthly mean O_3 abundances over the USA will increase by 1 to 6 ppb from a tripling of these emissions between 1985 and 2010; and Collins *et al.* (2000) project a 3 ppb increase from 1990 to 2015 in monthly mean O_3 over north-west Europe due to rising North American emissions. The impact of metropolitan pollution will expand over the coming decades as urban areas grow and use of resources intensifies.

What is new in this IPCC assessment is the extension of these projections to the year 2100, whereupon the cumulative impact of all Northern Hemisphere emissions, not just those immediately upwind, may for some scenarios double O_3 abundances over the northern mid-latitudes. Surface O_3 abundances during July over the industrialised continents of the Northern Hemisphere are about 40 ppb with 2000 emissions; and under SRES scenarios A2 and A1FI they would reach 45 to 50 ppb with 2030 emissions, 60 ppb with 2060 emissions, and >70 ppb with 2100 emissions. Since regional ozone episodes start with these background levels and build upon them with local smog production, it may be impossible under these circumstances to achieve a clean-air standard of <80 ppb over most populated regions. This problem reaches across continental boundaries and couples emissions of NO_x on a hemispheric scale. In the 21st century a global perspective will be needed to meet regional air quality objectives. The impact of this threatened degradation of air quality upon societal behaviour and policy decisions will possibly change the balance of future emissions impacting climate change (e.g., more fuel burn (CO_2) to achieve lower NO_x as in aviation; Penner *et al.*, 1999).

Under some emission scenarios, the large increases in tropospheric O_3 combined with the decreases in OH may alter the oxidation rate and the degradation paths for hydrocarbons and other hazardous substances. The damage caused by higher O_3 levels to both crops and natural systems needs to be assessed, and societal responses to this threat would likely change the emissions scenarios evaluated here (e.g., the current SRES scenarios anticipate the societal demand to control urban aerosols and acid rain by substantially cutting sulphur emissions) .

Coupling between atmospheric chemistry, the biosphere, and the climate are not at the stage that these feedbacks can be included in this assessment. There are indications, however, that the evolution of natural emissions and physical climate projected over the next century will change the baseline atmospheric chemistry and lead to altered biosphere-atmosphere exchanges and continued atmospheric change independent of anthropogenic emissions.

CHAPTER 5

INCINERATION AND OPEN BURNING OF WASTE

5 INCINERATION AND OPEN BURNING OF WASTE

5.1 INTRODUCTION

Waste incineration is defined as the combustion of solid and liquid waste in controlled incineration facilities. Modern refuse combustors have tall stacks and specially designed combustion chambers, which provide high combustion temperatures, long residence times, and efficient waste agitation while introducing air for more complete combustion. Types of waste incinerated include municipal solid waste (MSW), industrial waste, hazardous waste, clinical waste and sewage sludge[1]. The practice of MSW incineration is currently more common in developed countries, while it is common for both developed and developing countries to incinerate clinical waste.

Emissions from waste incineration without energy recovery are reported in the Waste Sector, while emissions from incineration with energy recovery are reported in the Energy Sector, both with a distinction between fossil and biogenic carbon dioxide (CO_2) emissions. The methodology described in this chapter is applicable in general both to incineration with and without energy recovery. Co-firing of specific waste fractions with other fuels is not addressed in this chapter, as co-firing is covered in Volume 2, Energy. Emissions from agricultural residue burning are considered in the AFOLU Sector, Chapter 5 of Volume 4.

Open burning of waste can be defined as the combustion of unwanted combustible materials such as paper, wood, plastics, textiles, rubber, waste oils and other debris in nature (open-air) or in open dumps, where smoke and other emissions are released directly into the air without passing through a chimney or stack. Open burning can also include incineration devices that do not control the combustion air to maintain an adequate temperature and do not provide sufficient residence time for complete combustion. This waste management practice is used in many developing countries while in developed countries open burning of waste may either be strictly regulated, or otherwise occur more frequently in rural areas than in urban areas.

Incineration and open burning of waste are sources of greenhouse gas emissions, like other types of combustion. Relevant gases emitted include CO_2, methane (CH_4) and nitrous oxide (N_2O). Normally, emissions of CO_2 from waste incineration are more significant than CH_4 and N_2O emissions.

Consistent with the *1996 Guidelines* (IPCC, 1997), only CO_2 emissions resulting from oxidation, during incineration and open burning of carbon in waste of fossil origin (e.g., plastics, certain textiles, rubber, liquid solvents, and waste oil) are considered net emissions and should be included in the national CO_2 emissions estimate. The CO_2 emissions from combustion of biomass materials (e.g., paper, food, and wood waste) contained in the waste are biogenic emissions and should not be included in national total emission estimates. However, if incineration of waste is used for energy purposes, both fossil and biogenic CO_2 emissions should be estimated. Only fossil CO_2 should be included in national emissions under Energy Sector while biogenic CO_2 should be reported as an information item also in the Energy Sector. Moreover, if combustion, or any other factor, is causing long term decline in the total carbon embodied in living biomass (e.g., forests), this net release of carbon should be evident in the calculation of CO_2 emissions described in the Agriculture, Forestry and Other Land Use (AFOLU) Volume of the *2006 Guidelines*.

This chapter provides guidance on methodological choices for estimating and reporting CO_2, CH_4 and N_2O emissions from incineration and open burning of all types of combustible waste. Where possible, default values for activity data, emission factors and other parameters are provided.

Traditional air pollutants from combustion - non-methane volatile organic compounds (NMVOCs), carbon monoxide (CO), nitrogen oxides (NO_x), sulphur oxides (SO_x) - are covered by existing emission inventory systems. Therefore, the IPCC does not provide new methodologies for these gases here, but recommends that national experts or inventory compilers use existing published methods under international agreements. Some key examples of the current literature providing methods include EMEP/CORINAIR Guidebook (EMEP 2004), US EPA's Compilation of Air Pollutant Emissions Factors, AP-42, Fifth Edition (USEPA, 1995), EPA Emission Inventory Improvement Program Technical Report Series, Vol. III Chapter 16: Open Burning (USEPA, 2001).

The estimation of indirect N_2O emissions, resulting from the conversion of nitrogen deposition to soils due to NO_x emissions from waste incineration and open burning, is addressed in Section 5.4.3 of this chapter. General background

[1] Waste generation, composition and management practices, including waste incineration and open burning, are addressed in detail in Chapter 2 of this volume.

A report of Working Group I of the Intergovernmental Panel on Climate Change

Summary for Policymakers

Miller (eds.)]. Cambridge University Press, Cambridge, United Kingdom and New York, NY, USA.

Introduction

The Working Group I contribution to the IPCC Fourth Assessment Report describes progress in understanding of the human and natural drivers of climate change,[1] observed climate change, climate processes and attribution, and estimates of projected future climate change. It builds upon past IPCC assessments and incorporates new findings from the past six years of research. Scientific progress since the Third Assessment Report (TAR) is based upon large amounts of new and more comprehensive data, more sophisticated analyses of data, improvements in understanding of processes and their simulation in models and more extensive exploration of uncertainty ranges.

The basis for substantive paragraphs in this Summary for Policymakers can be found in the chapter sections specified in curly brackets.

Human and Natural Drivers of Climate Change

Changes in the atmospheric abundance of greenhouse gases and aerosols, in solar radiation and in land surface properties alter the energy balance of the climate system. These changes are expressed in terms of radiative forcing,[2] which is used to compare how a range of human and natural factors drive warming or cooling influences on global climate. Since the TAR, new observations and related modelling of greenhouse gases, solar activity, land surface properties and some aspects of aerosols have led to improvements in the quantitative estimates of radiative forcing.

Global atmospheric concentrations of carbon dioxide, methane and nitrous oxide have increased markedly as a result of human activities since 1750 and now far exceed pre-industrial values determined from ice cores spanning many thousands of years (see Figure SPM.1). The global increases in carbon dioxide concentration are due primarily to fossil fuel use and land use change, while those of methane and nitrous oxide are primarily due to agriculture. {2.3, 6.4, 7.3}

- Carbon dioxide is the most important anthropogenic greenhouse gas (see Figure SPM.2). The global atmospheric concentration of carbon dioxide has increased from a pre-industrial value of about 280 ppm to 379 ppm[3] in 2005. The atmospheric concentration of carbon dioxide in 2005 exceeds by far the natural range over the last 650,000 years (180 to 300 ppm) as determined from ice cores. The annual carbon dioxide concentration growth rate was larger during the last 10 years (1995–2005 average: 1.9 ppm per year), than it has been since the beginning of continuous direct atmospheric measurements (1960–2005 average: 1.4 ppm per year) although there is year-to-year variability in growth rates. {2.3, 7.3}

- The primary source of the increased atmospheric concentration of carbon dioxide since the pre-industrial period results from fossil fuel use, with land-use change providing another significant but smaller contribution. Annual fossil carbon dioxide emissions[4] increased from an average of 6.4 [6.0 to 6.8][5] GtC (23.5 [22.0 to 25.0] $GtCO_2$) per year in the 1990s to 7.2 [6.9 to 7.5] GtC (26.4 [25.3 to 27.5] $GtCO_2$) per year in 2000–2005 (2004 and 2005 data are interim estimates). Carbon dioxide emissions associated with land-use change

[1] *Climate change* in IPCC usage refers to any change in climate over time, whether due to natural variability or as a result of human activity. This usage differs from that in the United Nations Framework Convention on Climate Change, where climate change refers to a change of climate that is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and that is in addition to natural climate variability observed over comparable time periods.

[2] *Radiative forcing* is a measure of the influence that a factor has in altering the balance of incoming and outgoing energy in the Earth-atmosphere system and is an index of the importance of the factor as a potential climate change mechanism. Positive forcing tends to warm the surface while negative forcing tends to cool it. In this report, radiative forcing values are for 2005 relative to pre-industrial conditions defined at 1750 and are expressed in watts per square metre (W m^{-2}). See Glossary and Section 2.2 for further details.

[3] ppm (parts per million) or ppb (parts per billion, 1 billion = 1,000 million) is the ratio of the number of greenhouse gas molecules to the total number of molecules of dry air. For example, 300 ppm means 300 molecules of a greenhouse gas per million molecules of dry air.

[4] Fossil carbon dioxide emissions include those from the production, distribution and consumption of fossil fuels and as a by-product from cement production. An emission of 1 GtC corresponds to 3.67 $GtCO_2$.

[5] In general, uncertainty ranges for results given in this Summary for Policymakers are 90% uncertainty intervals unless stated otherwise, that is, there is an estimated 5% likelihood that the value could be above the range given in square brackets and 5% likelihood that the value could be below that range. Best estimates are given where available. Assessed uncertainty intervals are not always symmetric about the corresponding best estimate. Note that a number of uncertainty ranges in the Working Group I TAR corresponded to 2 standard deviations (95%), often using expert judgement.

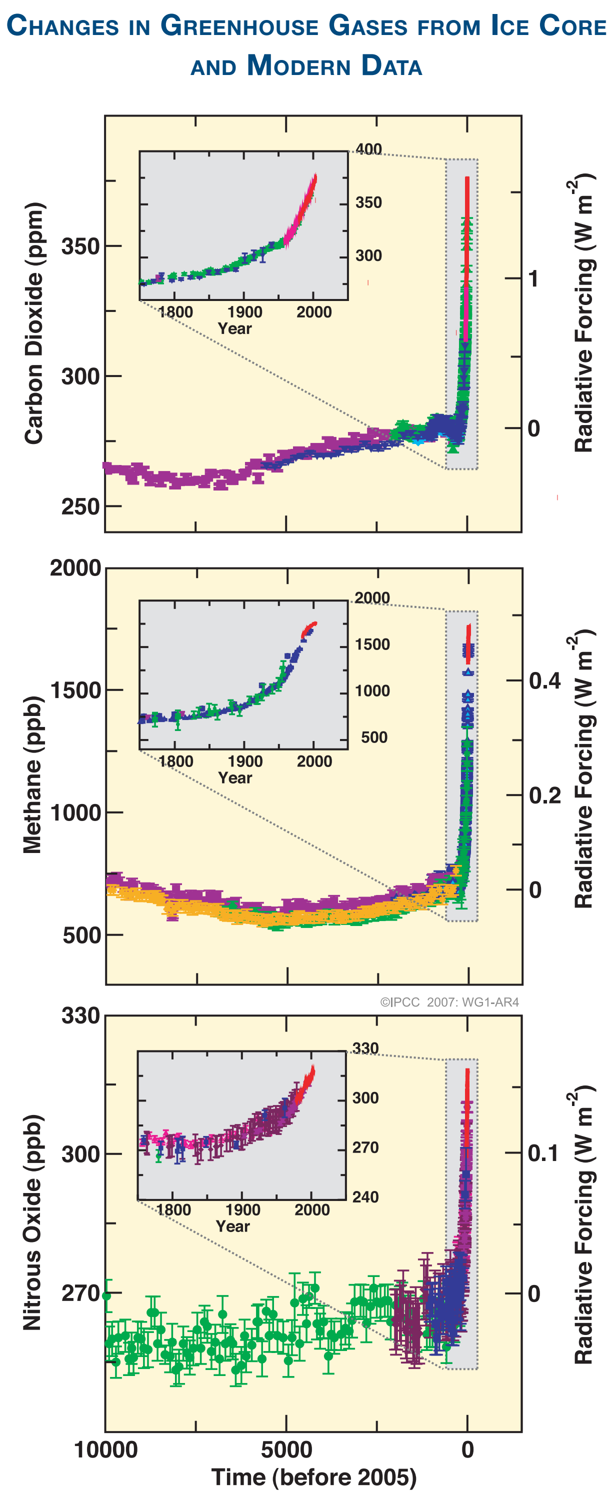

Figure SPM.1. *Atmospheric concentrations of carbon dioxide, methane and nitrous oxide over the last 10,000 years (large panels) and since 1750 (inset panels). Measurements are shown from ice cores (symbols with different colours for different studies) and atmospheric samples (red lines). The corresponding radiative forcings are shown on the right hand axes of the large panels. {Figure 6.4}*

are estimated to be 1.6 [0.5 to 2.7] GtC (5.9 [1.8 to 9.9] $GtCO_2$) per year over the 1990s, although these estimates have a large uncertainty. {7.3}

- The global atmospheric concentration of methane has increased from a pre-industrial value of about 715 ppb to 1732 ppb in the early 1990s, and was 1774 ppb in 2005. The atmospheric concentration of methane in 2005 exceeds by far the natural range of the last 650,000 years (320 to 790 ppb) as determined from ice cores. Growth rates have declined since the early 1990s, consistent with total emissions (sum of anthropogenic and natural sources) being nearly constant during this period. It is *very likely*[6] that the observed increase in methane concentration is due to anthropogenic activities, predominantly agriculture and fossil fuel use, but relative contributions from different source types are not well determined. {2.3, 7.4}

- The global atmospheric nitrous oxide concentration increased from a pre-industrial value of about 270 ppb to 319 ppb in 2005. The growth rate has been approximately constant since 1980. More than a third of all nitrous oxide emissions are anthropogenic and are primarily due to agriculture. {2.3, 7.4}

The understanding of anthropogenic warming and cooling influences on climate has improved since the TAR, leading to *very high confidence*[7] that the global average net effect of human activities since 1750 has been one of warming, with a radiative forcing of +1.6 [+0.6 to +2.4] W m^{-2} (see Figure SPM.2). {2.3., 6.5, 2.9}

- The combined radiative forcing due to increases in carbon dioxide, methane, and nitrous oxide is +2.30 [+2.07 to +2.53] W m^{-2}, and its rate of increase during the industrial era is *very likely* to have been unprecedented in more than 10,000 years (see Figures

[6] In this Summary for Policymakers, the following terms have been used to indicate the assessed likelihood, using expert judgement, of an outcome or a result: *Virtually certain* > 99% probability of occurrence, *Extremely likely* > 95%, *Very likely* > 90%, *Likely* > 66%, *More likely than not* > 50%, *Unlikely* < 33%, *Very unlikely* < 10%, *Extremely unlikely* < 5% (see Box TS.1 for more details).

[7] In this Summary for Policymakers the following levels of confidence have been used to express expert judgements on the correctness of the underlying science: *very high confidence* represents at least a 9 out of 10 chance of being correct; *high confidence* represents about an 8 out of 10 chance of being correct (see Box TS.1)

A report accepted by Working Group I of the Intergovernmental Panel on Climate Change but not approved in detail

"Acceptance" of IPCC Reports at a Session of the Working Group or Panel signifies that the material has not been subject to line-by-line discussion and agreement, but nevertheless presents a comprehensive, objective and balanced view of the subject matter.

Table of Contents

TS.1 Introduction

In the six years since the IPCC's Third Assessment Report (TAR), significant progress has been made in understanding past and recent climate change and in projecting future changes. These advances have arisen from large amounts of new data, more sophisticated analyses of data, improvements in the understanding and simulation of physical processes in climate models and more extensive exploration of uncertainty ranges in model results. The increased confidence in climate science provided by these developments is evident in this Working Group I contribution to the IPCC's Fourth Assessment Report.

While this report provides new and important policy-relevant information on the scientific understanding of climate change, the complexity of the climate system and the multiple interactions that determine its behaviour impose limitations on our ability to understand fully the future course of Earth's global climate. There is still an incomplete physical understanding of many components of the climate system and their role in climate change. Key uncertainties include aspects of the roles played by clouds, the cryosphere, the oceans, land use and couplings between climate and biogeochemical cycles. The areas of science covered in this report continue to undergo rapid progress and it should be recognised that the present assessment reflects scientific understanding based on the peer-reviewed literature available in mid-2006.

The key findings of the IPCC Working Group I assessment are presented in the Summary for Policymakers. This Technical Summary provides a more detailed overview of the scientific basis for those findings and provides a road map to the chapters of the underlying report. It focuses on key findings, highlighting what is new since the TAR. The structure of the Technical Summary is as follows:

- Section 2: an overview of current scientific understanding of the natural and anthropogenic drivers of changes in climate;
- Section 3: an overview of observed changes in the climate system (including the atmosphere, oceans and cryosphere) and their relationships to physical processes;
- Section 4: an overview of explanations of observed climate changes based on climate models and physical understanding, the extent to which climate change can be attributed to specific causes and a new evaluation of climate sensitivity to greenhouse gas increases;
- Section 5: an overview of projections for both near- and far-term climate changes including the time scales of responses to changes in forcing, and probabilistic information about future climate change; and
- Section 6: a summary of the most robust findings and the key uncertainties in current understanding of physical climate change science.

Each paragraph in the Technical Summary reporting substantive results is followed by a reference in curly brackets to the corresponding chapter section(s) of the underlying report where the detailed assessment of the scientific literature and additional information can be found.

TS.2 Changes in Human and Natural Drivers of Climate

The Earth's global mean climate is determined by incoming energy from the Sun and by the properties of the Earth and its atmosphere, namely the reflection, absorption and emission of energy within the atmosphere and at the surface. Although changes in received solar energy (e.g., caused by variations in the Earth's orbit around the Sun) inevitably affect the Earth's energy budget, the properties of the atmosphere and surface are also important and these may be affected by climate feedbacks. The importance of climate feedbacks is evident in the nature of past climate changes as recorded in ice cores up to 650,000 years old.

Changes have occurred in several aspects of the atmosphere and surface that alter the global energy budget of the Earth and can therefore cause the climate to change. Among these are increases in greenhouse gas concentrations that act primarily to increase the atmospheric absorption of outgoing radiation, and increases in aerosols (microscopic airborne particles or droplets) that act to reflect and absorb incoming solar radiation and change cloud radiative properties. Such changes cause a radiative forcing of the climate system.[1] Forcing agents can differ considerably from one another in terms of the magnitudes of forcing, as well as spatial and temporal features. Positive and negative radiative forcings contribute to increases and decreases, respectively, in

[1] 'Radiative forcing' is a measure of the influence a factor has in altering the balance of incoming and outgoing energy in the Earth-atmosphere system and is an index of the importance of the factor as a potential climate change mechanism. Positive forcing tends to warm the surface while negative forcing tends to cool it. In this report, radiative forcing values are for changes relative to a pre-industrial background at 1750, are expressed in Watts per square metre (W m^{-2}) and, unless otherwise noted, refer to a global and annual average value. See Glossary for further details.

Box TS.1: Treatment of Uncertainties in the Working Group I Assessment

The importance of consistent and transparent treatment of uncertainties is clearly recognised by the IPCC in preparing its assessments of climate change. The increasing attention given to formal treatments of uncertainty in previous assessments is addressed in Section 1.6. To promote consistency in the general treatment of uncertainty across all three Working Groups, authors of the Fourth Assessment Report have been asked to follow a brief set of guidance notes on determining and describing uncertainties in the context of an assessment.[2] This box summarises the way that Working Group I has applied those guidelines and covers some aspects of the treatment of uncertainty specific to material assessed here.

Uncertainties can be classified in several different ways according to their origin. Two primary types are 'value uncertainties' and 'structural uncertainties'. Value uncertainties arise from the incomplete determination of particular values or results, for example, when data are inaccurate or not fully representative of the phenomenon of interest. Structural uncertainties arise from an incomplete understanding of the processes that control particular values or results, for example, when the conceptual framework or model used for analysis does not include all the relevant processes or relationships. Value uncertainties are generally estimated using statistical techniques and expressed probabilistically. Structural uncertainties are generally described by giving the authors' collective judgment of their confidence in the correctness of a result. In both cases, estimating uncertainties is intrinsically about describing the limits to knowledge and for this reason involves expert judgment about the state of that knowledge. A different type of uncertainty arises in systems that are either chaotic or not fully deterministic in nature and this also limits our ability to project all aspects of climate change.

The scientific literature assessed here uses a variety of other generic ways of categorising uncertainties. Uncertainties associated with 'random errors' have the characteristic of decreasing as additional measurements are accumulated, whereas those associated with 'systematic errors' do not. In dealing with climate records, considerable attention has been given to the identification of systematic errors or unintended biases arising from data sampling issues and methods of analysing and combining data. Specialised statistical methods based on quantitative analysis have been developed for the detection and attribution of climate change and for producing probabilistic projections of future climate parameters. These are summarised in the relevant chapters.

The uncertainty guidance provided for the Fourth Assessment Report draws, for the first time, a careful distinction between levels of confidence in scientific understanding and the likelihoods of specific results. This allows authors to express high confidence that an event is extremely unlikely (e.g., rolling a dice twice and getting a six both times), as well as high confidence that an event is about as likely as not (e.g., a tossed coin coming up heads). Confidence and likelihood as used here are distinct concepts but are often linked in practice.

The standard terms used to define levels of confidence in this report are as given in the IPCC Uncertainty Guidance Note, namely:

Confidence Terminology	Degree of confidence in being correct
Very high confidence	At least 9 out of 10 chance
High confidence	About 8 out of 10 chance
Medium confidence	About 5 out of 10 chance
Low confidence	About 2 out of 10 chance
Very low confidence	Less than 1 out of 10 chance

Note that 'low confidence' and 'very low confidence' are only used for areas of major concern and where a risk-based perspective is justified.

Chapter 2 of this report uses a related term 'level of scientific understanding' when describing uncertainties in different contributions to radiative forcing. This terminology is used for consistency with the Third Assessment Report, and the basis on which the authors have determined particular levels of scientific understanding uses a combination of approaches consistent with the uncertainty guidance note as explained in detail in Section 2.9.2 and Table 2.11.

(continued)

[2] The IPCC Uncertainty Guidance Note is included in Supplementary Material for this report.

The standard terms used in this report to define the likelihood of an outcome or result where this can be estimated probabilistically are:

Likelihood Terminology	Likelihood of the occurrence/ outcome
Virtually certain	> 99% probability
Extremely likely	> 95% probability
Very likely	> 90% probability
Likely	> 66% probability
More likely than not	> 50% probability
About as likely as not	33 to 66% probability
Unlikely	< 33% probability
Very unlikely	< 10% probability
Extremely unlikely	< 5% probability
Exceptionally unlikely	< 1% probability

The terms 'extremely likely', 'extremely unlikely' and 'more likely than not' as defined above have been added to those given in the IPCC Uncertainty Guidance Note in order to provide a more specific assessment of aspects including attribution and radiative forcing.

Unless noted otherwise, values given in this report are assessed best estimates and their uncertainty ranges are 90% confidence intervals (i.e., there is an estimated 5% likelihood of the value being below the lower end of the range or above the upper end of the range). Note that in some cases the nature of the constraints on a value, or other information available, may indicate an asymmetric distribution of the uncertainty range around a best estimate. In such cases, the uncertainty range is given in square brackets following the best estimate.

global average surface temperature. This section updates the understanding of estimated anthropogenic and natural radiative forcings.

The overall response of global climate to radiative forcing is complex due to a number of positive and negative feedbacks that can have a strong influence on the climate system (see e.g., Sections 4.5 and 5.4). Although water vapour is a strong greenhouse gas, its concentration in the atmosphere changes in response to changes in surface climate and this must be treated as a feedback effect and not as a radiative forcing. This section also summarises changes in the surface energy budget and its links to the hydrological cycle. Insights into the effects of agents such as aerosols on precipitation are also noted.

TS.2.1 Greenhouse Gases

The dominant factor in the radiative forcing of climate in the industrial era is the increasing concentration of various greenhouse gases in the atmosphere. Several of the major greenhouse gases occur naturally but increases in their atmospheric concentrations over the last 250 years are due largely to human activities. Other greenhouse gases are entirely the result of human activities. The contribution of each greenhouse gas to radiative forcing over a particular period of time is determined by the change in its concentration in the atmosphere over that period and the effectiveness of the gas in perturbing the radiative balance. Current atmospheric concentrations of the different greenhouse gases considered in this report vary by more than eight orders of magnitude (factor of 10^8), and their radiative efficiencies vary by more than four orders of magnitude (factor of 10^4), reflecting the enormous diversity in their properties and origins.

The current concentration of a greenhouse gas in the atmosphere is the net result of the history of its past emissions and removals from the atmosphere. The gases and aerosols considered here are emitted to the atmosphere by human activities or are formed from precursor species emitted to the atmosphere. These emissions are offset by chemical and physical removal processes. With the important exception of carbon dioxide (CO_2), it is generally the case that these processes remove a specific fraction of the amount of a gas in the atmosphere each year and the inverse of this removal rate gives the mean lifetime for that gas. In some cases, the removal rate may vary with gas concentration or other atmospheric properties (e.g., temperature or background chemical conditions).

Long-lived greenhouse gases (LLGHGs), for example, CO_2, methane (CH_4) and nitrous oxide (N_2O), are chemically stable and persist in the atmosphere over time scales of a decade to centuries or longer, so that their emission has a long-term influence on climate. Because these gases are long lived, they become well mixed throughout the atmosphere much faster than they are removed and their global concentrations can be accurately estimated from data at a few locations. Carbon dioxide does not have a specific lifetime because it is continuously cycled between the atmosphere, oceans and land biosphere and its net removal from the atmosphere involves a range of processes with different time scales.

Short-lived gases (e.g., sulphur dioxide and carbon monoxide) are chemically reactive and generally removed by natural oxidation processes in the atmosphere, by removal at the surface or by washout in precipitation; their concentrations are hence highly variable. Ozone is a significant greenhouse gas that is formed and destroyed by chemical reactions involving other species in the atmosphere. In the troposphere, the human influence on ozone occurs primarily through changes in precursor gases that lead to its formation, whereas in the stratosphere, the human influence has been primarily through changes in ozone removal rates caused by chlorofluorocarbons (CFCs) and other ozone-depleting substances.

TS.2.1.1 Changes in Atmospheric Carbon Dioxide, Methane and Nitrous Oxide

Current concentrations of atmospheric CO_2 and CH_4 far exceed pre-industrial values found in polar ice core records of atmospheric composition dating back 650,000 years. Multiple lines of evidence confirm that the post-industrial rise in these gases does not stem from natural mechanisms (see Figure TS.1 and Figure TS.2). {2.3, 6.3–6.5, FAQ 7.1}

The total radiative forcing of the Earth's climate due to increases in the concentrations of the LLGHGs CO_2, CH_4 and N_2O, and *very likely* the rate of increase in the total forcing due to these gases over the period since 1750, are unprecedented in more than 10,000 years (Figure TS.2). It is *very likely* that the sustained rate of increase in the combined radiative forcing from these greenhouse gases of about +1 W m^{-2} over the past four decades is at least six times faster than at any time during the two millennia before the Industrial Era, the period for which ice core data have the required temporal resolution. The radiative forcing due to these LLGHGs has the highest level of confidence of any forcing agent. {2.3, 6.4}

GLACIAL-INTERGLACIAL ICE CORE DATA

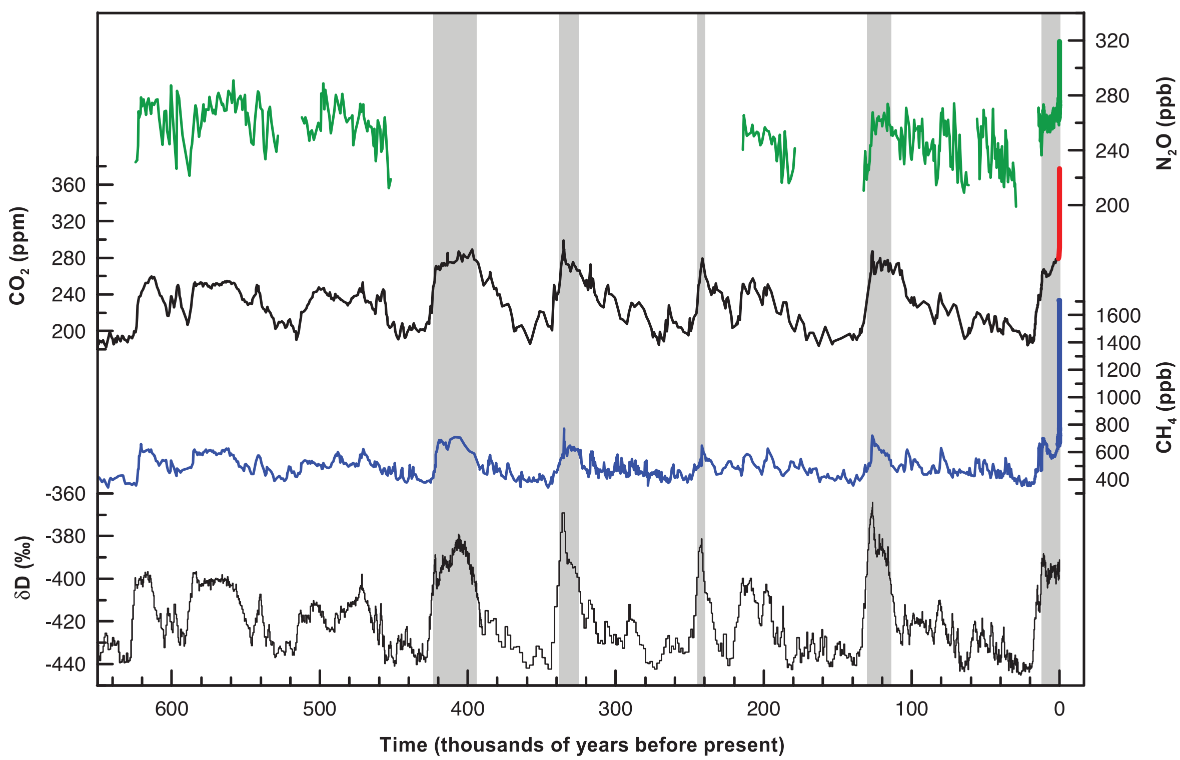

Figure TS.1. *Variations of deuterium (δD) in antarctic ice, which is a proxy for local temperature, and the atmospheric concentrations of the greenhouse gases carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O) in air trapped within the ice cores and from recent atmospheric measurements. Data cover 650,000 years and the shaded bands indicate current and previous interglacial warm periods. {Adapted from Figure 6.3}*

Changes in Greenhouse Gases from Ice Core and Modern Data

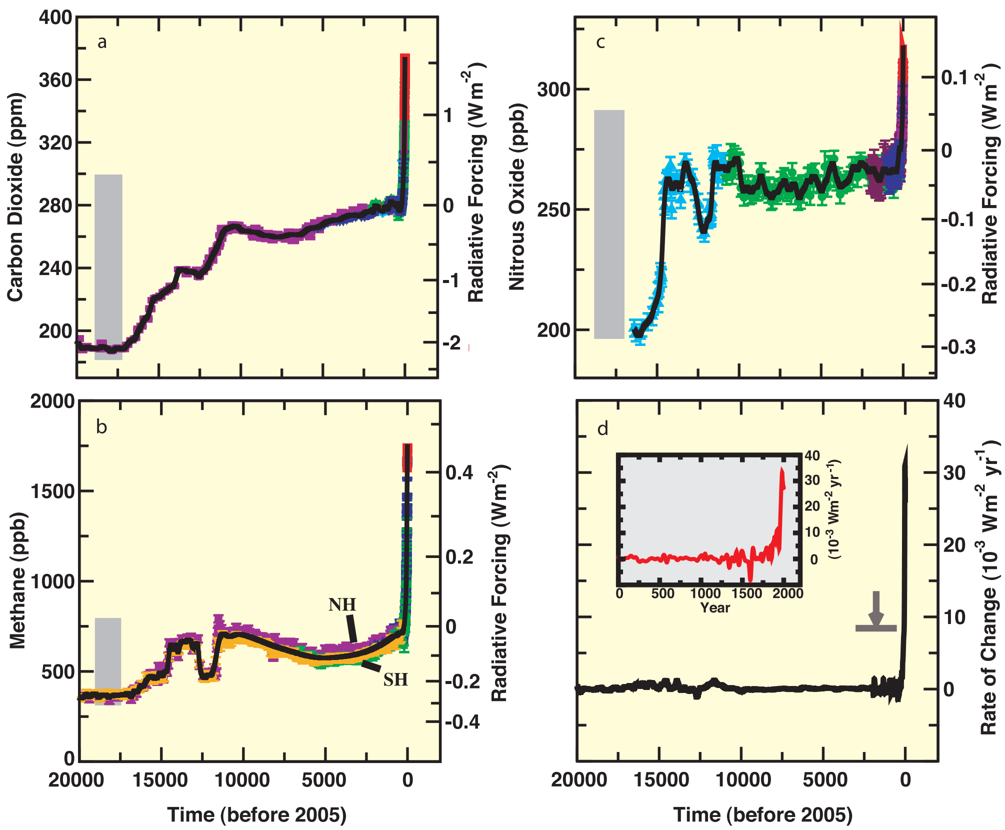

Figure TS.2. *The concentrations and radiative forcing by (a) carbon dioxide (CO_2), (b) methane (CH_4), (c) nitrous oxide (N_2O) and (d) the rate of change in their combined radiative forcing over the last 20,000 years reconstructed from antarctic and Greenland ice and firn data (symbols) and direct atmospheric measurements (panels a,b,c, red lines). The grey bars show the reconstructed ranges of natural variability for the past 650,000 years. The rate of change in radiative forcing (panel d, black line) has been computed from spline fits to the concentration data. The width of the age spread in the ice data varies from about 20 years for sites with a high accumulation of snow such as Law Dome, Antarctica, to about 200 years for low-accumulation sites such as Dome C, Antarctica. The arrow shows the peak in the rate of change in radiative forcing that would result if the anthropogenic signals of CO_2, CH_4, and N_2O had been smoothed corresponding to conditions at the low-accumulation Dome C site. The negative rate of change in forcing around 1600 shown in the higher-resolution inset in panel d results from a CO_2 decrease of about 10 ppm in the Law Dome record. {Figure 6.4}*

The concentration of atmospheric CO_2 has increased from a pre-industrial value of about 280 ppm to 379 ppm in 2005. Atmospheric CO_2 concentration increased by only 20 ppm over the 8000 years prior to industrialisation; multi-decadal to centennial-scale variations were less than 10 ppm and *likely* due mostly to natural processes. However, since 1750, the CO_2 concentration has risen by nearly 100 ppm. The annual CO_2 growth rate was larger during the last 10 years (1995–2005 average: 1.9 ppm yr^{-1}) than it has been since continuous direct atmospheric measurements began (1960–2005 average: 1.4 ppm yr^{-1}). {2.3, 6.4, 6.5}

Increases in atmospheric CO_2 since pre-industrial times are responsible for a radiative forcing of +1.66 ± 0.17 W m^{-2}; a contribution which dominates all other radiative forcing agents considered in this report. For the decade from 1995 to 2005, the growth rate of CO_2 in the atmosphere led to a 20% increase in its radiative forcing. {2.3, 6.4, 6.5}

Emissions of CO_2 from fossil fuel use and from the effects of land use change on plant and soil carbon are the primary sources of increased atmospheric CO_2. Since 1750, it is estimated that about 2/3rds of anthropogenic CO_2 emissions have come from fossil fuel burning and about 1/3rd from land use change. About 45% of this CO_2 has remained in the atmosphere, while about 30% has been taken up by the oceans and the remainder has been taken up by the terrestrial biosphere. About half of a CO_2 pulse to the atmosphere is removed over a time scale of 30 years; a further 30% is removed within a few centuries; and the remaining 20% will typically stay in the atmosphere for many thousands of years. {7.3}

In recent decades, emissions of CO_2 have continued to increase (see Figure TS.3). Global annual fossil

CO_2 emissions[3] increased from an average of 6.4 ± 0.4 GtC yr^{-1} in the 1990s to 7.2 ± 0.3 GtC yr^{-1} in the period 2000 to 2005. Estimated CO_2 emissions associated with land use change, averaged over the 1990s, were[4] 0.5 to 2.7 GtC yr^{-1}, with a central estimate of 1.6 Gt yr^{-1}. Table TS.1 shows the estimated budgets of CO_2 in recent decades. {2.3, 6.4, 7.3, FAQ 7.1}

Since the 1980s, natural processes of CO_2 uptake by the terrestrial biosphere (i.e., the residual land sink in Table TS.1) and by the oceans have removed about 50% of anthropogenic emissions (i.e., fossil CO_2 emissions and land use change flux in Table TS.1). These removal processes are influenced by the atmospheric CO_2 concentration and by changes in climate. Uptake by the oceans and the terrestrial biosphere have been similar in magnitude but the terrestrial biosphere uptake is more variable and was higher in the 1990s than in the 1980s by about 1 GtC yr^{-1}. Observations demonstrate that dissolved CO_2 concentrations in the surface ocean (pCO_2) have been increasing nearly everywhere, roughly following the atmospheric CO_2 increase but with large regional and temporal variability. {5.4, 7.3}

Carbon uptake and storage in the terrestrial biosphere arise from the net difference between uptake due to vegetation growth, changes in reforestation and sequestration, and emissions due to heterotrophic respiration, harvest, deforestation, fire, damage by pollution and other disturbance factors affecting biomass and soils. Increases and decreases in fire frequency in different regions have affected net carbon uptake, and in boreal regions, emissions due to fires appear to have increased over recent decades. Estimates of net CO_2 surface fluxes from inverse studies using networks of atmospheric data demonstrate significant land uptake in the mid-latitudes of the Northern Hemisphere (NH) and near-zero land-atmosphere fluxes in the tropics, implying that tropical deforestation is approximately balanced by regrowth. {7.3}

Short-term (interannual) variations observed in the atmospheric CO_2 growth rate are primarily controlled by changes in the flux of CO_2 between the atmosphere and the terrestrial biosphere, with a smaller but significant fraction due to variability in ocean fluxes (see Figure TS.3). Variability in the terrestrial biosphere flux is driven by climatic fluctuations, which affect the uptake of CO_2 by plant growth and the return of CO_2 to the atmosphere by the decay of organic material through heterotrophic respiration and fires. El Niño-Southern Oscillation (ENSO) events are a major source of interannual variability in atmospheric CO_2 growth rate, due to their effects on fluxes through land and sea surface temperatures, precipitation and the incidence of fires. {7.3}

The direct effects of increasing atmospheric CO_2 on large-scale terrestrial carbon uptake cannot be quantified reliably at present. Plant growth can be stimulated by increased atmospheric CO_2 concentrations and by nutrient deposition (fertilization effects). However, most experiments and studies show that such responses appear to be relatively short lived and strongly coupled

Table TS.1. *Global carbon budget. By convention, positive values are CO_2 fluxes (GtC yr^{-1}) into the atmosphere and negative values represent uptake from the atmosphere (i.e., 'CO_2 sinks'). Fossil CO_2 emissions for 2004 and 2005 are based on interim estimates. Due to the limited number of available studies, for the net land-to-atmosphere flux and its components, uncertainty ranges are given as 65% confidence intervals and do not include interannual variability (see Section 7.3). NA indicates that data are not available.*

	1980s	1990s	2000–2005
Atmospheric increase	3.3 ± 0.1	3.2 ± 0.1	4.1 ± 0.1
Fossil carbon dioxide emissions	5.4 ± 0.3	6.4 ± 0.4	7.2 ± 0.3
Net ocean-to-atmosphere flux	–1.8 ± 0.8	–2.2 ± 0.4	–2.2 ± 0.5
Net land-to-atmosphere flux	–0.3 ± 0.9	–1.0 ± 0.6	–0.9 ± 0.6
Partitioned as follows			
Land use change flux	1.4 (0.4 to 2.3)	1.6 (0.5 to 2.7)	NA
Residual land sink	–1.7 (–3.4 to 0.2)	–2.6 (–4.3 to –0.9)	NA

[3] Fossil CO_2 emissions include those from the production, distribution and consumption of fossil fuels and from cement production. Emission of 1 GtC corresponds to 3.67 $GtCO_2$.

[4] As explained in Section 7.3, uncertainty ranges for land use change emissions, and hence for the full carbon cycle budget, can only be given as 65% confidence intervals.

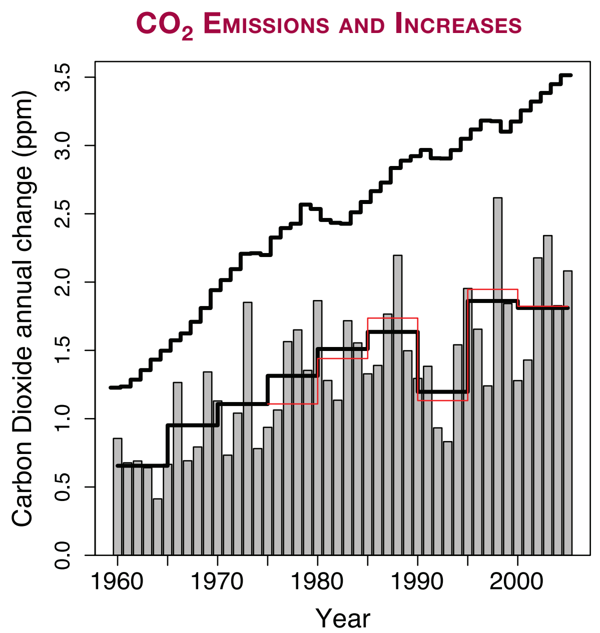

Figure TS.3. *Annual changes in global mean CO_2 concentration (grey bars) and their five-year means from two different measurement networks (red and lower black stepped lines). The five-year means smooth out short-term perturbations associated with strong ENSO events in 1972, 1982, 1987 and 1997. Uncertainties in the five-year means are indicated by the difference between the red and lower black lines and are of order 0.15 ppm. The upper stepped line shows the annual increases that would occur if all fossil fuel emissions stayed in the atmosphere and there were no other emissions. {Figure 7.4}*

to other effects such as availability of water and nutrients. Likewise, experiments and studies of the effects of climate (temperature and moisture) on heterotrophic respiration of litter and soils are equivocal. Note that the effect of climate change on carbon uptake is addressed separately in section TS.5.4. {7.3}

The CH_4 abundance in 2005 of about 1774 ppb is more than double its pre-industrial value. Atmospheric CH_4 concentrations varied slowly between 580 and 730 ppb over the last 10,000 years, but increased by about 1000 ppb in the last two centuries, representing the fastest changes in this gas over at least the last 80,000 years. In the late 1970s and early 1980s, CH_4 growth rates displayed maxima above 1% yr^{-1}, but since the early 1990s have decreased significantly and were close to zero for the six-year period from 1999 to 2005. Increases in CH_4 abundance occur when emissions exceed removals. The recent decline in growth rates implies that emissions now approximately match removals, which are due primarily to oxidation by the hydroxyl radical (OH). Since the TAR, new studies using two independent tracers (methyl chloroform and ^{14}CO) suggest no significant long-term change in the global abundance of OH. Thus, the slowdown in the atmospheric CH_4 growth rate since about 1993 is *likely* due to the atmosphere approaching an equilibrium during a period of near-constant total emissions. {2.3, 7.4, FAQ 7.1}

Increases in atmospheric CH_4 concentrations since pre-industrial times have contributed a radiative forcing of +0.48 ± 0.05 W m^{-2}. Among greenhouse gases, this forcing remains second only to that of CO_2 in magnitude. {2.3}

Current atmospheric CH_4 levels are due to continuing anthropogenic emissions of CH_4, which are greater than natural emissions. Total CH_4 emissions can be well determined from observed concentrations and independent estimates of removal rates. Emissions from individual sources of CH_4 are not as well quantified as the total emissions but are mostly biogenic and include emissions from wetlands, ruminant animals, rice agriculture and biomass burning, with smaller contributions from industrial sources including fossil fuel-related emissions. This knowledge of CH_4 sources, combined with the small natural range of CH_4 concentrations over the past 650,000 years (Figure TS.1) and their dramatic increase since 1750 (Figure TS.2), make it *very likely* that the observed long-term changes in CH_4 are due to anthropogenic activity. {2.3, 6.4, 7.4}

In addition to its slowdown over the last 15 years, the growth rate of atmospheric CH_4 has shown high interannual variability, which is not yet fully explained. The largest contributions to interannual variability during the 1996 to 2001 period appear to be variations in emissions from wetlands and biomass burning. Several studies indicate that wetland CH_4 emissions are highly sensitive to temperature and are also affected by hydrological changes. Available model estimates all indicate increases in wetland emissions due to future climate change but vary widely in the magnitude of such a positive feedback effect. {7.4}

The N_2O concentration in 2005 was 319 ppb, about 18% higher than its pre-industrial value. Nitrous oxide increased approximately linearly by about 0.8 ppb yr^{-1} over the past few decades. Ice core data show that the atmospheric concentration of N_2O varied by less than about 10 ppb for 11,500 years before the onset of the industrial period. {2.3, 6.4, 6.5}

The increase in N_2O since the pre-industrial era now contributes a radiative forcing of +0.16 ± 0.02 W m^{-2} and is due primarily to human activities, particularly agriculture and associated land use change. Current estimates are that about 40% of total N_2O emissions are anthropogenic but individual source estimates remain subject to significant uncertainties. {2.3, 7.4}

TS.2.1.3 Changes in Atmospheric Halocarbons, Stratospheric Ozone, Tropospheric Ozone and Other Gases

CFCs and hydrochlorofluorocarbons (HCFCs) are greenhouse gases that are purely anthropogenic in origin and used in a wide variety of applications. Emissions of these gases have decreased due to their phase-out under the Montreal Protocol, and the atmospheric concentrations of CFC-11 and CFC-113 are now decreasing due to natural removal processes. Observations in polar firn cores since the TAR have now extended the available time series information for some of these greenhouse gases. Ice core and *in situ* data confirm that industrial sources are the cause of observed atmospheric increases in CFCs and HCFCs. {2.3}

The Montreal Protocol gases contributed +0.32 ± 0.03 W m^{-2} to direct radiative forcing in 2005, with CFC-12 continuing to be the third most important long-lived radiative forcing agent. These gases as a group contribute about 12% of the total forcing due to LLGHGs. {2.3}

The concentrations of industrial fluorinated gases covered by the Kyoto Protocol (hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), sulphur hexafluoride (SF_6)) are relatively small but are increasing rapidly. Their total radiative forcing in 2005 was +0.017 W m^{-2}. {2.3}

Tropospheric ozone is a short-lived greenhouse gas produced by chemical reactions of precursor species in the atmosphere and with large spatial and temporal variability. Improved measurements and modelling have advanced the understanding of chemical precursors that lead to the formation of tropospheric ozone, mainly carbon monoxide, nitrogen oxides (including sources and possible long-term trends in lightning) and formaldehyde. Overall, current models are successful in describing the principal features of the present global tropospheric ozone distribution on the basis of underlying processes. New satellite and *in situ* measurements provide important global constraints for these models; however, there is less confidence in their ability to reproduce the changes in ozone associated with large changes in emissions or climate, and in the simulation of observed long-term trends in ozone concentrations over the 20th century. {7.4}

Tropospheric ozone radiative forcing is estimated to be +0.35 [+0.25 to +0.65] W m^{-2} with a *medium* level of scientific understanding. The best estimate of this radiative forcing has not changed since the TAR. Observations show that trends in tropospheric ozone during the last few decades vary in sign and magnitude at many locations, but there are indications of significant upward trends at low latitudes. Model studies of the radiative forcing due to the increase in tropospheric ozone since pre-industrial times have increased in complexity and comprehensiveness compared with models used in the TAR. {2.3, 7.4}

Changes in tropospheric ozone are linked to air quality and climate change. A number of studies have shown that summer daytime ozone concentrations correlate strongly with temperature. This correlation appears to reflect contributions from temperature-dependent biogenic volatile organic carbon emissions, thermal decomposition of peroxyacetylnitrate, which acts as a reservoir for nitrogen oxides (NO_x), and association of high temperatures with regional stagnation. Anomalously hot and stagnant conditions during the summer of 1988 were responsible for the highest surface-level ozone year on record in the north-eastern USA. The summer heat wave in Europe in 2003 was also associated with exceptionally high local ozone at the surface. {Box 7.4}

The radiative forcing due to the destruction of stratospheric ozone is caused by the Montreal Protocol gases and is re-evaluated to be –0.05 ± 0.10 W m^{-2}, weaker than in the TAR, with a medium level of scientific understanding. The trend of greater and greater depletion of global stratospheric ozone observed during the 1980s and 1990s is no longer occurring; however, global stratospheric ozone is still about 4% below pre-1980 values and it is not yet clear whether ozone recovery has begun. In addition to the chemical destruction of ozone, dynamical changes may have contributed to NH mid-latitude ozone reduction. {2.3}

Direct emission of water vapour by human activities makes a negligible contribution to radiative forcing. However, as global mean temperatures increase, tropospheric water vapour concentrations increase and this represents a key feedback but not a forcing of climate change. Direct emission of water to the atmosphere by anthropogenic activities, mainly irrigation, is a possible forcing factor but corresponds to less than 1% of the natural sources of atmospheric water vapour. The direct injection of water vapour into the atmosphere from fossil fuel combustion is significantly lower than that from agricultural activity. {2.5}

Based on chemical transport model studies, the radiative forcing from increases in stratospheric water vapour due to oxidation of CH_4 is estimated to be +0.07 ± 0.05 W m^{-2}. The level of scientific understanding is low because the contribution of CH_4 to the corresponding vertical structure of the water vapour change near the tropopause is uncertain. Other potential human causes of stratospheric water vapour increases that could contribute to radiative forcing are poorly understood. {2.3}

TS.2.2 Aerosols

Direct aerosol radiative forcing is now considerably better quantified than previously and represents a major advance in understanding since the time of the TAR, when several components had a very low level of scientific understanding. A total direct aerosol radiative forcing combined across all aerosol types can now be given for the first time as –0.5 ± 0.4 W m^{-2}, with a medium-low level of scientific understanding. Atmospheric models have improved and many now represent all aerosol components of significance. Aerosols vary considerably in their properties that affect the extent to which they absorb and scatter radiation, and thus different types may have a net cooling or warming effect. Industrial aerosol consisting mainly of a mixture of sulphates, organic and black carbon, nitrates and industrial dust is clearly discernible over many continental regions of the NH. Improved *in situ*, satellite and surface-based measurements (see Figure TS.4) have enabled verification of global aerosol model simulations. These improvements allow quantification of the total direct aerosol radiative forcing for the first time, representing an important advance since the TAR. The direct radiative forcing for individual species remains less certain and is estimated from models to be –0.4 ± 0.2 W m^{-2} for sulphate, –0.05 ± 0.05 W m^{-2} for fossil fuel organic carbon, +0.2 ± 0.15 W m^{-2} for fossil fuel black carbon, +0.03 ± 0.12 W m^{-2} for biomass burning, –0.1 ± 0.1 W m^{-2} for nitrate and –0.1 ± 0.2 W m^{-2} for mineral dust. Two recent emission inventory studies support data from ice cores and suggest that global anthropogenic sulphate emissions decreased over the 1980 to 2000 period and that the geographic distribution of sulphate forcing has also changed. {2.4, 6.6}

Significant changes in the estimates of the direct radiative forcing due to biomass-burning, nitrate and mineral dust aerosols have occurred since the TAR. For biomass-burning aerosol, the estimated direct radiative forcing is now revised from being negative to near zero due to the estimate being strongly influenced by the occurrence of these aerosols over clouds. For the first time, the radiative forcing due to nitrate aerosol is given. For mineral dust, the range in the direct radiative forcing is reduced due to a reduction in the estimate of its anthropogenic fraction. {2.4}

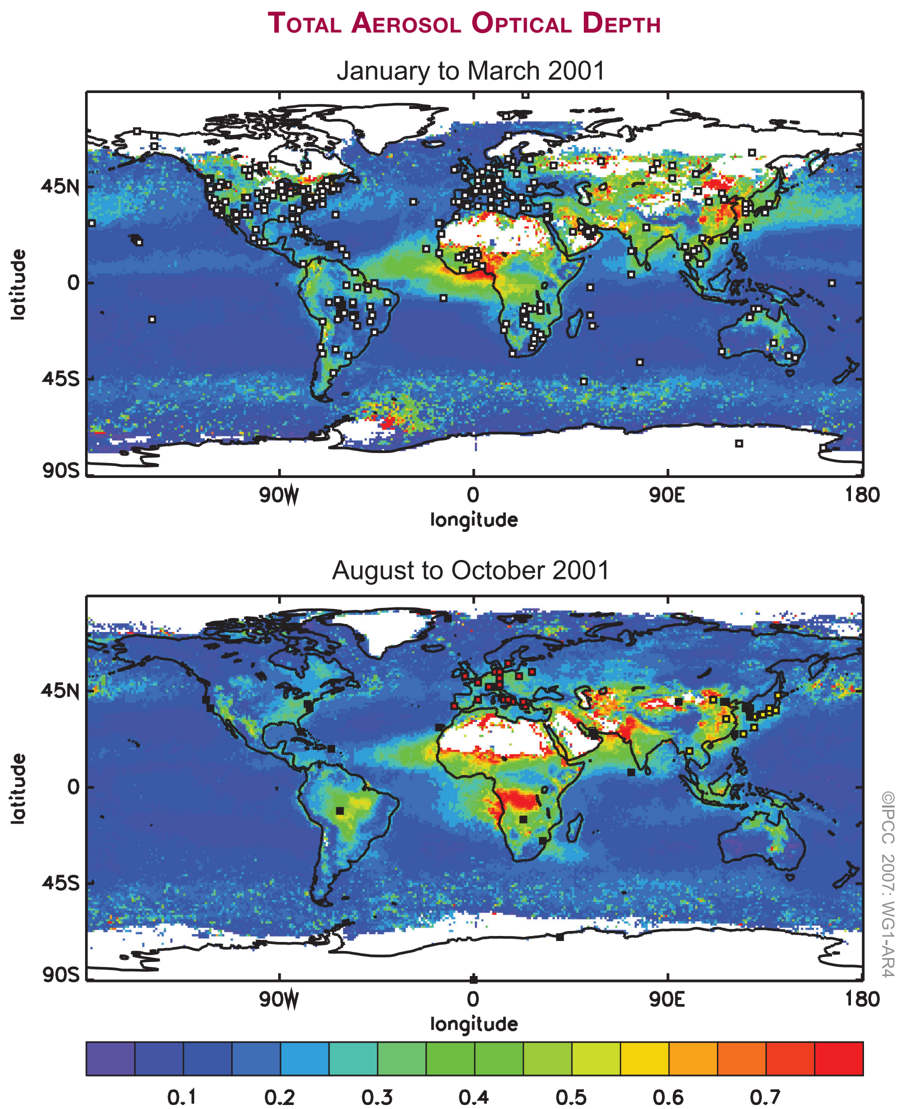

Figure TS.4. *(Top) The total aerosol optical depth (due to natural plus anthropogenic aerosols) at a mid-visible wavelength determined by satellite measurements for January to March 2001 and (bottom) August to October 2001, illustrating seasonal changes in industrial and biomass-burning aerosols. Data are from satellite measurements, complemented by two different kinds of ground-based measurements at locations shown in the two panels (see Section 2.4.2 for details). {Figure 2.11}*

Anthropogenic aerosols effects on water clouds cause an indirect cloud albedo effect (referred to as the first indirect effect in the TAR), which has a best estimate for the first time of –0.7 [–0.3 to –1.8] W m^{-2}. The number of global model estimates of the albedo effect for liquid water clouds has increased substantially since the TAR, and the estimates have been evaluated in a more rigorous way. The estimate for this radiative forcing comes from multiple model studies incorporating more aerosol species and describing aerosol-cloud interaction processes in greater detail. Model studies including more aerosol species or constrained by satellite observations tend to yield a relatively weaker cloud albedo effect. Despite the advances and progress since the TAR and the reduction in the spread of the estimate of the forcing, there remain large uncertainties in both measurements and modelling of processes, leading to a low level of scientific understanding, which is an elevation from the very low rank in the TAR. {2.4, 7.5, 9.2}

Other effects of aerosol include a cloud lifetime effect, a semi-direct effect and aerosol-ice cloud interactions. These are considered to be part of the climate response rather than radiative forcings. {2.4, 7.5}

TS.2.3 Aviation Contrails and Cirrus, Land Use and Other Effects

Persistent linear contrails from global aviation contribute a small radiative forcing of +0.01 [+0.003 to +0.03] W m^{-2}, with a low level of scientific understanding. This best estimate is smaller than the estimate in the TAR. This difference results from new observations of contrail cover and reduced estimates of contrail optical depth. No best estimates are available for the net forcing from spreading contrails. Their effects on cirrus cloudiness and the global effect of aviation aerosol on background cloudiness remain unknown. {2.6}

Human-induced changes in land cover have increased the global surface albedo, leading to a radiative forcing of –0.2 ± 0.2 W m^{-2}, the same as in the TAR, with a medium-low level of scientific understanding. Black carbon aerosols deposited on snow reduce the surface albedo and are estimated to yield an associated radiative forcing of +0.1 ± 0.1 W m^{-2}, with a low level of scientific understanding. Since the TAR, a number of estimates of the forcing from land use changes have been made, using better techniques, exclusion of feedbacks in the evaluation and improved incorporation of large-scale observations. Uncertainties in the estimate include mapping and characterisation of present-day vegetation and historical state, parametrization of surface radiation processes and biases in models' climate variables. The presence of soot particles in snow leads to a decrease in the albedo of snow and a positive forcing, and could affect snowmelt. Uncertainties are large regarding the manner in which soot is incorporated in snow and the resulting optical properties. {2.5}

The impacts of land use change on climate are expected to be locally significant in some regions, but are small at the global scale in comparison with greenhouse gas warming. Changes in the land surface (vegetation, soils, water) resulting from human activities can significantly affect local climate through shifts in radiation, cloudiness, surface roughness and surface temperatures. Changes in vegetation cover can also have a substantial effect on surface energy and water balance at the regional scale. These effects involve non-radiative processes (implying that they cannot be quantified by a radiative forcing) and have a very low level of scientific understanding. {2.5, 7.2, 9.3, Box 11.4}

The release of heat from anthropogenic energy production can be significant over urban areas but is not significant globally. {2.5}

TS.2.4 Radiative Forcing Due to Solar Activity and Volcanic Eruptions

Continuous monitoring of total solar irradiance now covers the last 28 years. The data show a well-established 11-year cycle in irradiance that varies by 0.08% from solar cycle minima to maxima, with no significant long-term trend. New data have more accurately quantified changes in solar spectral fluxes over a broad range of wavelengths in association with changing solar activity. Improved calibrations using high-quality overlapping measurements have also contributed to a better understanding. Current understanding of solar physics and the known sources of irradiance variability suggest comparable irradiance levels during the past two solar cycles, including at solar minima. The primary known cause of contemporary irradiance variability is the presence on the Sun's disk of sunspots (compact, dark features where radiation is locally depleted) and faculae (extended bright features where radiation is locally enhanced). {2.7}

The estimated direct radiative forcing due to changes in the solar output since 1750 is +0.12 [+0.06 to +0.3] W m^{-2}, which is less than half of the estimate given in the TAR, with a low level of scientific understanding. The reduced radiative forcing estimate comes from a re-evaluation of the long-term change in solar irradiance since 1610 (the Maunder Minimum) based upon: a new reconstruction using a model of solar magnetic flux variations that does not invoke geomagnetic, cosmogenic or stellar proxies; improved understanding of recent solar variations and their relationship to physical processes; and re-evaluation of the variations of Sun-like stars. While this leads to an elevation in the level of scientific understanding from very low in the TAR to low in this assessment, uncertainties remain large because of the lack of direct observations and incomplete understanding of solar variability mechanisms over long time scales. {2.7, 6.6}

Empirical associations have been reported between solar-modulated cosmic ray ionization of the atmosphere and global average low-level cloud cover but evidence for a systematic indirect solar effect remains ambiguous. It has been suggested that galactic cosmic rays with sufficient energy to reach the troposphere could alter the population of cloud condensation nuclei and hence microphysical cloud properties (droplet number and concentration), inducing changes in cloud processes analogous to the indirect cloud albedo effect of tropospheric aerosols and thus causing an indirect solar forcing of climate. Studies have probed various correlations with clouds in particular regions or using limited cloud types or limited time periods; however, the cosmic ray time series does not appear to correspond to global total cloud cover after 1991 or to global low-level cloud cover after 1994. Together with the lack of a proven physical mechanism and the plausibility of other causal factors affecting changes in cloud cover, this makes the association between galactic cosmic ray-induced changes in aerosol and cloud formation controversial. {2.7}

Explosive volcanic eruptions greatly increase the concentration of stratospheric sulphate aerosols. A single eruption can thereby cool global mean climate for a few years. Volcanic aerosols perturb both the stratosphere and surface/troposphere radiative energy budgets and climate in an episodic manner, and many past events are evident in ice core observations of sulphate as well as temperature records. There have been no explosive volcanic events since the 1991 Mt. Pinatubo eruption capable of injecting significant material to the stratosphere. However, the potential exists for volcanic eruptions much larger than the 1991 Mt. Pinatubo eruption, which could produce larger radiative forcing and longer-term cooling of the climate system. {2.7, 6.4, 6.6, 9.2}

TS.2.5 Net Global Radiative Forcing, Global Warming Potentials and Patterns of Forcing

The understanding of anthropogenic warming and cooling influences on climate has improved since the TAR, leading to *very high confidence* that the effect of human activities since 1750 has been a net positive forcing of +1.6 [+0.6 to +2.4] W m^{-2}. Improved understanding and better quantification of the forcing mechanisms since the TAR make it possible to derive a combined net anthropogenic radiative forcing for the first time. Combining the component values for each forcing agent and their uncertainties yields the probability distribution of the combined anthropogenic radiative forcing estimate shown in Figure TS.5; the most likely value is about an order of magnitude larger than the estimated radiative forcing from changes in solar irradiance. Since the range in the estimate is +0.6 to +2.4 W m^{-2}, there is very high confidence in the net positive radiative forcing of the climate system due to human activity. The LLGHGs together contribute +2.63 ± 0.26 W m^{-2}, which is the dominant radiative forcing term and has the highest level of scientific understanding. In contrast, the total direct aerosol, cloud albedo and surface albedo effects that contribute negative forcings are less well understood and have larger uncertainties. The range in the net estimate is increased by the negative forcing terms, which have larger uncertainties than the positive terms. The nature of the uncertainty in the estimated cloud albedo effect introduces a noticeable asymmetry in the distribution. Uncertainties in the distribution include structural aspects (e.g., representation of extremes in the component values, absence of any weighting of the radiative forcing mechanisms, possibility of unaccounted for but as yet unquantified radiative forcings) and statistical aspects (e.g., assumptions about the types of distributions describing component uncertainties). {2.7, 2.9}

The Global Warming Potential (GWP) is a useful metric for comparing the potential climate impact of the emissions of different LLGHGs (see Table TS.2). Global Warming Potentials compare the integrated radiative forcing over a specified period (e.g., 100 years) from a unit mass pulse emission and are a way of comparing the potential climate change associated with emissions of different greenhouse gases. There are well-documented shortcomings of the GWP concept, particularly in using it to assess the impact of short-lived species. {2.10}

For the magnitude and range of realistic forcings considered, evidence suggests an approximately linear relationship between global mean radiative forcing and global mean surface temperature response. The spatial patterns of radiative forcing vary between different forcing agents. However, the spatial signature of the climate response is not generally expected to match that of the forcing. Spatial patterns of climate response

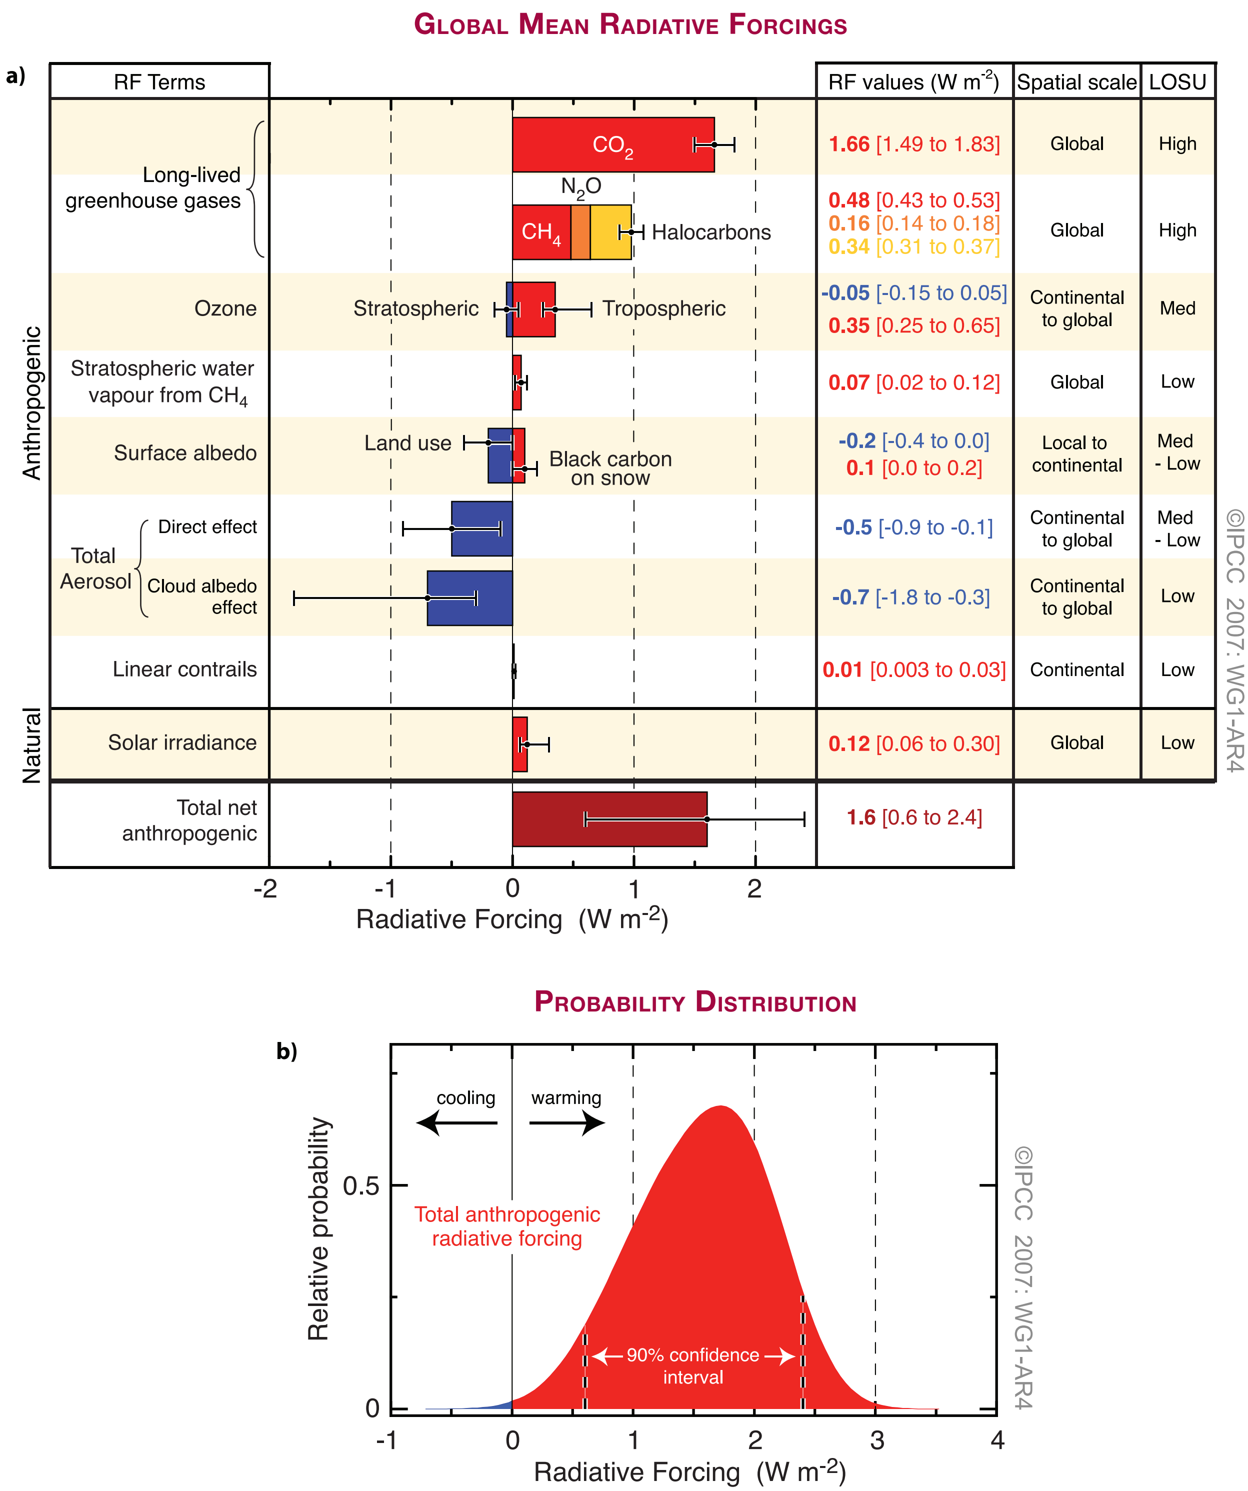

Figure TS.5. *(a) Global mean radiative forcings (RF) and their 90% confidence intervals in 2005 for various agents and mechanisms. Columns on the right-hand side specify best estimates and confidence intervals (RF values); typical geographical extent of the forcing (Spatial scale); and level of scientific understanding (LOSU) indicating the scientific confidence level as explained in Section 2.9. Errors for CH_4, N_2O and halocarbons have been combined. The net anthropogenic radiative forcing and its range are also shown. Best estimates and uncertainty ranges can not be obtained by direct addition of individual terms due to the asymmetric uncertainty ranges for some factors; the values given here were obtained from a Monte Carlo technique as discussed in Section 2.9. Additional forcing factors not included here are considered to have a very low LOSU. Volcanic aerosols contribute an additional form of natural forcing but are not included due to their episodic nature. The range for linear contrails does not include other possible effects of aviation on cloudiness. (b) Probability distribution of the global mean combined radiative forcing from all anthropogenic agents shown in (a). The distribution is calculated by combining the best estimates and uncertainties of each component. The spread in the distribution is increased significantly by the negative forcing terms, which have larger uncertainties than the positive terms. {2.9.1, 2.9.2; Figure 2.20}*

Notes:

‡ SAR refers to the IPCC Second Assessment Report (1995) used for reporting under the UNFCCC.

a The CO_2 response function used in this report is based on the revised version of the Bern Carbon cycle model used in Chapter 10 of this report (Bern2.5CC; Joos et al. 2001) using a background CO_2 concentration value of 378 ppm. The decay of a pulse of CO_2 with time t is given by

$$a_0 + \sum_{i=1}^{3} a_i \cdot e^{-t/\tau_i}$$ where $a_0 = 0.217$, $a_1 = 0.259$, $a_2 = 0.338$, $a_3 = 0.186$, $\tau_1 = 172.9$ years, $\tau_2 = 18.51$ years, and $\tau_3 = 1.186$ years, for $t < 1{,}000$ years.

b The radiative efficiency of CO_2 is calculated using the IPCC (1990) simplified expression as revised in the TAR, with an updated background concentration value of 378 ppm and a perturbation of +1 ppm (see Section 2.10.2).

c The perturbation lifetime for CH_4 is 12 years as in the TAR (see also Section 7.4). The GWP for CH_4 includes indirect effects from enhancements of ozone and stratospheric water vapour (see Section 2.10) .

d The assumed lifetime of 1000 years is a lower limit.

are largely controlled by climate processes and feedbacks. For example, sea ice-albedo feedbacks tend to enhance the high-latitude response. Spatial patterns of response are also affected by differences in thermal inertia between land and sea areas. {2.8, 9.2}

The pattern of response to a radiative forcing can be altered substantially if its structure is favourable for affecting a particular aspect of the atmospheric structure or circulation. Modelling studies and data comparisons suggest that mid- to high-latitude circulation patterns are *likely* to be affected by some forcings such as volcanic eruptions, which have been linked to changes in the Northern Annular Mode (NAM) and North Atlantic Oscillation (NAO) (see Section 3.1 and Box TS.2). Simulations also suggest that absorbing aerosols, particularly black carbon, can reduce the solar radiation reaching the surface and can warm the atmosphere at regional scales, affecting the vertical temperature profile and the large-scale atmospheric circulation. {2.8, 7.5, 9.2}

The spatial patterns of radiative forcings for ozone, aerosol direct effects, aerosol-cloud interactions and land use have considerable uncertainties. This is in contrast to the relatively high confidence in the spatial pattern of radiative forcing for the LLGHGs. The net positive radiative forcing in the Southern Hemisphere (SH) *very likely* exceeds that in the NH because of smaller aerosol concentrations in the SH. {2.9}

TS 2.6 Surface Forcing and the Hydrologic Cycle

Observations and models indicate that changes in the radiative flux at the Earth's surface affect the surface heat and moisture budgets, thereby involving the hydrologic cycle. Recent studies indicate that some forcing agents can influence the hydrologic cycle differently than others through their interactions with clouds. In particular, changes in aerosols may have affected precipitation and other aspects of the hydrologic cycle more strongly than other anthropogenic forcing agents. Energy deposited at the surface directly affects evaporation and sensible heat transfer. The instantaneous radiative flux change at the surface (hereafter called 'surface forcing') is a useful diagnostic tool for understanding changes in the heat and moisture surface budgets and the accompanying climate change. However, unlike radiative forcing, it cannot be used to quantitatively compare the effects of different agents on the equilibrium global mean surface temperature change. Net radiative forcing and surface forcing have different equator-to-pole gradients in the NH, and are different between the NH and SH. {2.9, 7.2, 7.5, 9.5}

TS.3 Observations of Changes in Climate

This assessment evaluates changes in the Earth's climate system, considering not only the atmosphere, but also the ocean and the cryosphere, as well as phenomena such as atmospheric circulation changes, in order to increase understanding of trends, variability and processes of climate change at global and regional scales. Observational records employing direct methods are of variable length as described below, with global temperature estimates now beginning as early as 1850. Observations of extremes of weather and climate are discussed, and observed changes in extremes are described. The consistency of observed changes among different climate variables that allows an increasingly comprehensive picture to be drawn is also described. Finally, palaeoclimatic information that generally employs indirect proxies to infer information about climate change over longer time scales (up to millions of years) is also assessed.

TS.3.1 Atmospheric Changes: Instrumental Record

This assessment includes analysis of global and hemispheric means, changes over land and ocean and distributions of trends in latitude, longitude and altitude. Since the TAR, improvements in observations and their calibration, more detailed analysis of methods and extended time series allow more in-depth analyses of changes including atmospheric temperature, precipitation, humidity, wind and circulation. Extremes of climate are a key expression of climate variability, and this assessment includes new data that permit improved insights into the changes in many types of extreme events including heat waves, droughts, heavy precipitation and tropical cyclones (including hurricanes and typhoons). {3.2–3.4, 3.8}

Furthermore, advances have occurred since the TAR in understanding how a number of seasonal and long-term anomalies can be described by patterns of climate variability. These patterns arise from internal interactions and from the differential effects on the atmosphere of land and ocean, mountains and large changes in heating. Their response is often felt in regions far removed from their physical source through atmospheric teleconnections associated with large-scale waves in the atmosphere. Understanding temperature and precipitation anomalies associated with the dominant patterns of climate variability is essential to understanding many regional climate anomalies and why these may differ from those at the global scale. Changes in storm tracks, the jet streams, regions of preferred blocking anticyclones and changes in monsoons can also occur in conjunction with these preferred patterns of variability. {3.5–3.7}

TS.3.1.1 Global Average Temperatures

2005 and 1998 were the warmest two years in the instrumental global surface air temperature record since 1850. Surface temperatures in 1998 were enhanced by the major 1997–1998 El Niño but no such strong anomaly was present in 2005. Eleven of the last 12 years (1995 to 2006) – the exception being 1996 – rank among the 12 warmest years on record since 1850. {3.2}

The global average surface temperature has increased, especially since about 1950. The updated 100-year trend (1906–2005) of 0.74°C ± 0.18°C is larger than the 100-year warming trend at the time of the TAR (1901–2000) of 0.6°C ± 0.2°C due to additional warm years. The total temperature increase from 1850-1899 to 2001-2005 is 0.76°C ± 0.19°C. The rate of warming averaged over the last 50 years (0.13°C ± 0.03°C per decade) is nearly twice that for the last 100 years. Three different global estimates all show consistent warming trends. There is also consistency between the data sets in their separate land and ocean domains, and between sea surface temperature (SST) and nighttime marine air temperature (see Figure TS.6). {3.2}

Recent studies confirm that effects of urbanisation and land use change on the global temperature record are negligible (less than 0.006°C per decade over land and zero over the ocean) as far as hemispheric- and continental-scale averages are concerned. All observations are subject to data quality and consistency checks to correct for potential biases. The real but local effects of urban areas are accounted for in the land temperature data sets used. Urbanisation and land use effects are not relevant to the widespread oceanic warming that has been observed. Increasing evidence suggests that urban heat island effects also affect precipitation, cloud and diurnal temperature range (DTR). {3.2}

The global average DTR has stopped decreasing. A decrease in DTR of approximately 0.1°C per decade was reported in the TAR for the period 1950 to 1993. Updated observations reveal that DTR has not changed from 1979 to 2004 as both day- and night time temperature have risen at about the same rate. The trends are highly variable from one region to another. {3.2}

New analyses of radiosonde and satellite measurements of lower- and mid-tropospheric temperature show warming rates that are generally consistent with each other and with those in the surface temperature record within their respective uncertainties for the periods 1958 to 2005 and 1979 to 2005. This largely resolves a discrepancy noted in the TAR (see Figure TS.7). The radiosonde record is markedly less spatially complete than the surface record and increasing evidence suggests that a number of radiosonde data sets are unreliable, especially in the tropics. Disparities remain among different tropospheric temperature trends estimated from satellite Microwave Sounding Unit (MSU) and advanced MSU measurements since 1979, and all likely still contain residual errors. However, trend estimates have been substantially improved and data set differences reduced since the TAR, through adjustments for changing satellites, orbit decay and drift in local crossing time (diurnal cycle effects). It appears that the satellite tropospheric temperature record is broadly consistent with surface temperature trends provided that the stratospheric influence on MSU channel 2 is accounted for. The range across different data sets of global surface warming since 1979 is 0.16°C to 0.18°C per decade, compared to 0.12°C to 0.19°C per decade for MSU-derived estimates of tropospheric temperatures. It is likely that there is increased warming with altitude from the surface through much of the troposphere in the tropics, pronounced cooling in the stratosphere, and a trend towards a higher tropopause. {3.4}

Stratospheric temperature estimates from adjusted radiosondes, satellites and reanalyses are all in qualitative agreement, with a cooling of between 0.3°C and 0.6°C per decade since 1979 (see Figure TS.7). Longer radiosonde records (back to 1958) also indicate stratospheric cooling but are subject to substantial instrumental uncertainties. The rate of cooling increased after 1979 but has slowed in the last decade. It is *likely* that radiosonde records overestimate stratospheric cooling, owing to changes in sondes not yet taken into account. The trends are not monotonic, because of stratospheric warming episodes that follow major volcanic eruptions. {3.4}

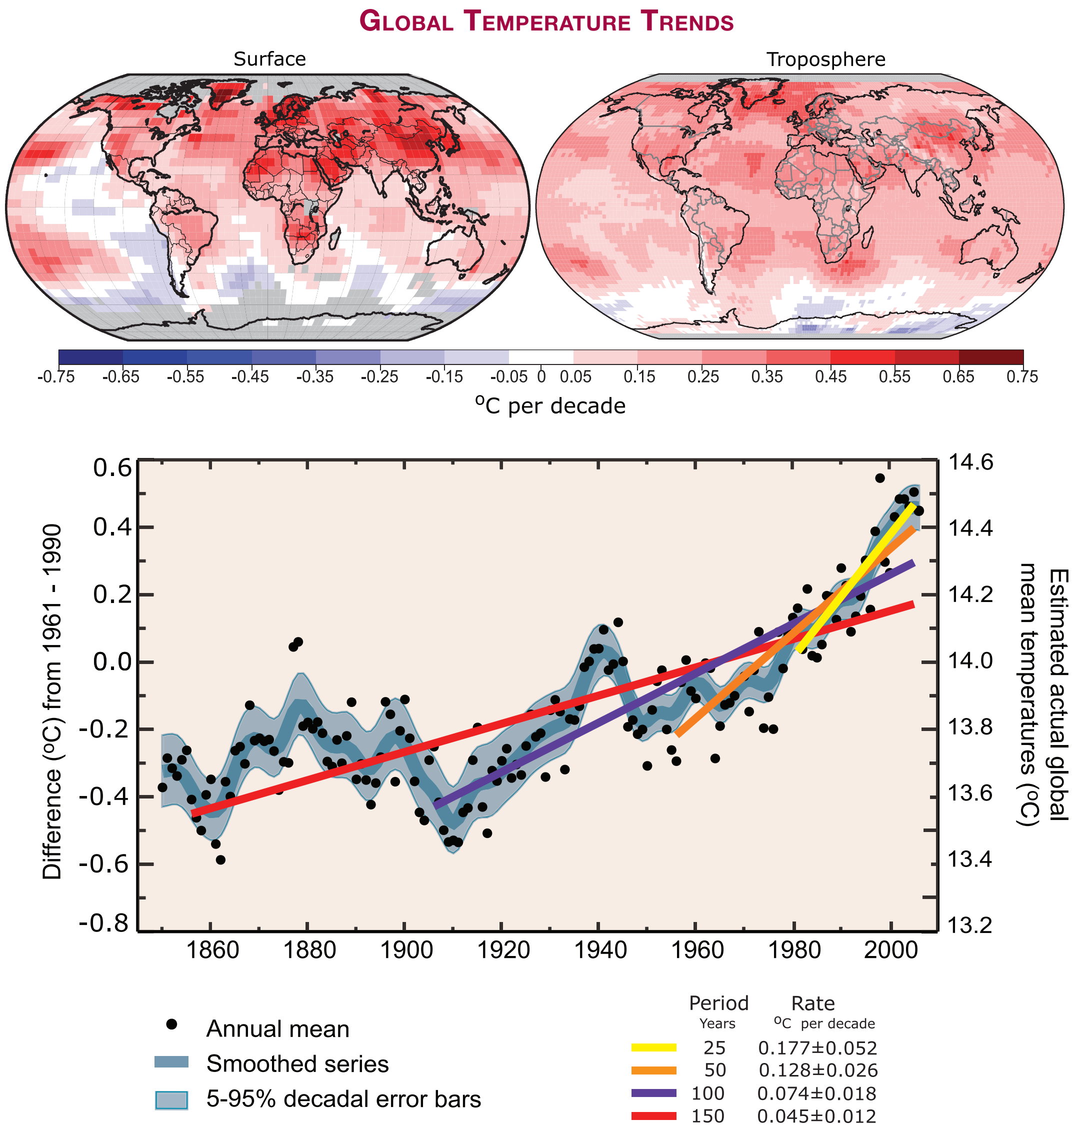

Figure TS.6. *(Top) Patterns of linear global temperature trends over the period 1979 to 2005 estimated at the surface (left), and for the troposphere from satellite records (right). Grey indicates areas with incomplete data. (Bottom) Annual global mean temperatures (black dots) with linear fits to the data. The left hand axis shows temperature anomalies relative to the 1961 to 1990 average and the right hand axis shows estimated actual temperatures, both in °C. Linear trends are shown for the last 25 (yellow), 50 (orange), 100 (purple) and 150 years (red). The smooth blue curve shows decadal variations (see Appendix 3.A), with the decadal 90% error range shown as a pale blue band about that line. The total temperature increase from the period 1850 to 1899 to the period 2001 to 2005 is 0.76°C ± 0.19°C. {FAQ 3.1, Figure 1.}*

TS.3.1.2 Spatial Distribution of Changes in Temperature, Circulation and Related Variables

Surface temperatures over land regions have warmed at a faster rate than over the oceans in both hemispheres. Longer records now available show significantly faster rates of warming over land than ocean in the past two decades (about 0.27°C vs. 0.13°C per decade). {3.2}

The warming in the last 30 years is widespread over the globe, and is greatest at higher northern latitudes. The greatest warming has occurred in the NH winter (DJF) and spring (MAM). Average arctic temperatures have been increasing at almost twice the rate of the rest of the world in the past 100 years. However, arctic temperatures are highly variable. A slightly longer arctic warm period, almost as warm as the present, was observed from 1925 to 1945, but its geographical distribution appears to have been different from the recent warming since its extent was not global. {3.2}

There is evidence for long-term changes in the large-scale atmospheric circulation, such as a poleward shift and strengthening of the westerly winds. Regional climate trends can be very different from the global average, reflecting changes in the circulations and interactions of the atmosphere and ocean and the other components of the climate system. Stronger mid-latitude westerly wind maxima have occurred in both hemispheres in most seasons from at least 1979 to the late 1990s, and poleward displacements of corresponding Atlantic and southern polar front jet streams have been documented. The westerlies in the NH increased from the 1960s to the 1990s but have since returned to values close to the long-term average. The increased strength of the westerlies in the NH changes the flow from oceans to continents, and is a major factor in the observed winter changes in storm tracks and related patterns of precipitation and temperature trends at mid- and high-latitudes. Analyses of wind and significant wave height support reanalysis-based evidence for changes in NH extratropical storms from the start of the reanalysis record in the late 1970s until the late 1990s. These changes are accompanied by a tendency towards stronger winter polar vortices throughout the troposphere and lower stratosphere. {3.2, 3.5}

Observed Air Temperatures

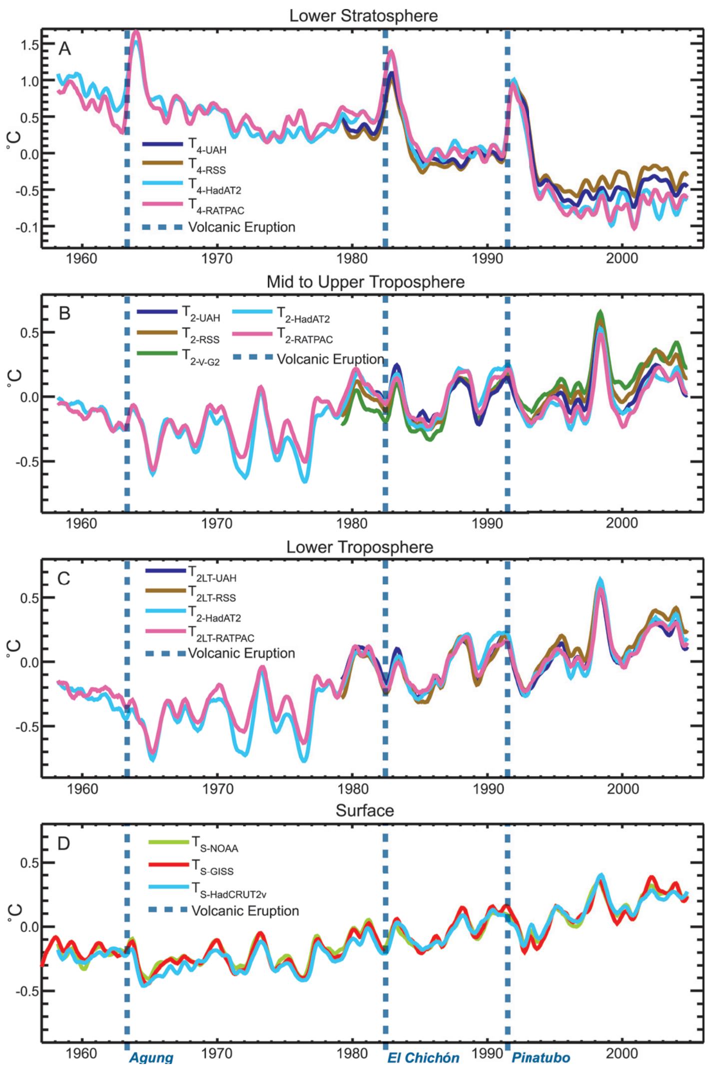

Figure TS.7. *Observed surface (D) and upper air temperatures for the lower troposphere (C), mid- to upper troposphere (B) and lower stratosphere (A), shown as monthly mean anomalies relative to the period 1979 to 1997 smoothed with a seven-month running mean filter. Dashed lines indicate the times of major volcanic eruptions. {Figure 3.17}*

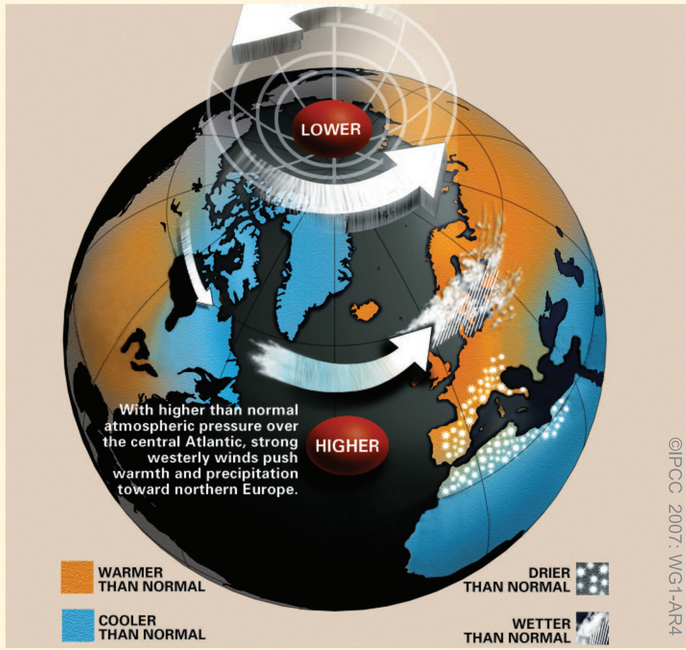
Many regional climate changes can be described in terms of preferred patterns of climate variability and therefore as changes in the occurrence of indices that characterise the strength and phase of these patterns. The importance, over all time scales, of fluctuations in the westerlies and storm tracks in the North Atlantic has often been noted, and these fluctuations are described by the NAO (see Box TS.2 for an explanation of this and other preferred patterns). The characteristics of fluctuations in the zonally averaged westerlies in the two hemispheres have more recently been described by their respective 'annular modes', the Northern and Southern Annular Modes (NAM and SAM). The observed changes can be expressed as a shift of the circulation towards the structure associated with one sign of these preferred patterns. The increased mid-latitude westerlies in the North Atlantic can be largely viewed as reflecting either NAO or NAM changes; multi-decadal variability is also evident in the Atlantic, both in the atmosphere and the ocean. In the SH, changes in circulation related to an increase in the SAM from the 1960s to the present are associated with strong warming over the Antarctic Peninsula and, to a lesser extent, cooling over parts of continental Antarctica. Changes have also been observed in ocean-atmosphere interactions in the Pacific. The ENSO is the dominant mode of global-scale variability on interannual time scales although there have been times when it is less apparent. The 1976–1977 climate shift, related to the phase change in the Pacific Decadal Oscillation (PDO) towards more El Niño events and changes in the evolution of ENSO, has affected many areas, including most tropical monsoons. For instance, over North America, ENSO and Pacific-

Box TS.2: Patterns (Modes) of Climate Variability

Analysis of atmospheric and climatic variability has shown that a significant component of it can be described in terms of fluctuations in the amplitude and sign of indices of a relatively small number of preferred patterns of variability. Some of the best known of these are:

- El Niño-Southern Oscillation (ENSO), a coupled fluctuation in the atmosphere and the equatorial Pacific Ocean, with preferred time scales of two to about seven years. ENSO is often measured by the difference in surface pressure anomalies between Tahiti and Darwin and the SSTs in the central and eastern equatorial Pacific. ENSO has global teleconnections.
- North Atlantic Oscillation (NAO), a measure of the strength of the Icelandic Low and the Azores High, and of the westerly winds between them, mainly in winter. The NAO has associated fluctuations in the storm track, temperature and precipitation from the North Atlantic into Eurasia (see Box TS.2, Figure 1).
- Northern Annular Mode (NAM), a winter fluctuation in the amplitude of a pattern characterised by low surface pressure in the Arctic and strong mid-latitude westerlies. The NAM has links with the northern polar vortex and hence the stratosphere.
- Southern Annular Mode (SAM), the fluctuation of a pattern with low antarctic surface pressure and strong mid-latitude westerlies, analogous to the NAM, but present year round.
- Pacific-North American (PNA) pattern, an atmospheric large-scale wave pattern featuring a sequence of tropospheric high- and low-pressure anomalies stretching from the subtropical west Pacific to the east coast of North America.
- Pacific Decadal Oscillation (PDO), a measure of the SSTs in the North Pacific that has a very strong correlation with the North Pacific Index (NPI) measure of the depth of the Aleutian Low. However, it has a signature throughout much of the Pacific.

Positive Phase of NAO and NAM



Box TS.2, Figure 1. *A schematic of the changes associated with the positive phase of the NAO and NAM. The changes in pressure and winds are shown, along with precipitation changes. Warm colours indicate areas that are warmer than normal and blue indicates areas that are cooler than normal.*

The extent to which all these preferred patterns of variability can be considered to be true modes of the climate system is a topic of active research. However, there is evidence that their existence can lead to larger-amplitude regional responses to forcing than would otherwise be expected. In particular, a number of the observed 20th-century climate changes can be viewed in terms of changes in these patterns. It is therefore important to test the ability of climate models to simulate them (see Section TS.4, Box TS.7) and to consider the extent to which observed changes related to these patterns are linked to internal variability or to anthropogenic climate change. {3.6, 8.4}

North American (PNA) teleconnection-related changes appear to have led to contrasting changes across the continent, as the western part has warmed more than the eastern part, while the latter has become cloudier and wetter. There is substantial low-frequency atmospheric variability in the Pacific sector over the 20th century, with extended periods of weakened (1900–1924; 1947–1976) as well as strengthened (1925–1946; 1977–2003) circulation. {3.2, 3.5, 3.6}

Changes in extremes of temperature are consistent with warming. Observations show widespread reductions in the number of frost days in mid-latitude regions, increases in the number of warm extremes (warmest 10% of days or nights) and a reduction in the number of daily cold extremes (coldest 10% of days or nights) (see Box TS.5). The most marked changes are for cold nights, which have declined over the 1951 to 2003 period for all regions where data are available (76% of the land). {3.8}

Heat waves have increased in duration beginning in the latter half of the 20th century. The record-breaking heat wave over western and central Europe in the summer of 2003 is an example of an exceptional recent extreme. That summer (JJA) was the warmest since comparable instrumental records began around 1780 (1.4°C above the previous warmest in 1807). Spring drying of the land surface over Europe was an important factor in the occurrence of the extreme 2003 temperatures. Evidence suggests that heat waves have also increased in frequency and duration in other locations. The very strong correlation between observed dryness and high temperatures over land in the tropics during summer highlights the important role moisture plays in moderating climate. {3.8, 3.9}

There is insufficient evidence to determine whether trends exist in such events as tornadoes, hail, lightning and dust storms which occur at small spatial scales. {3.8}

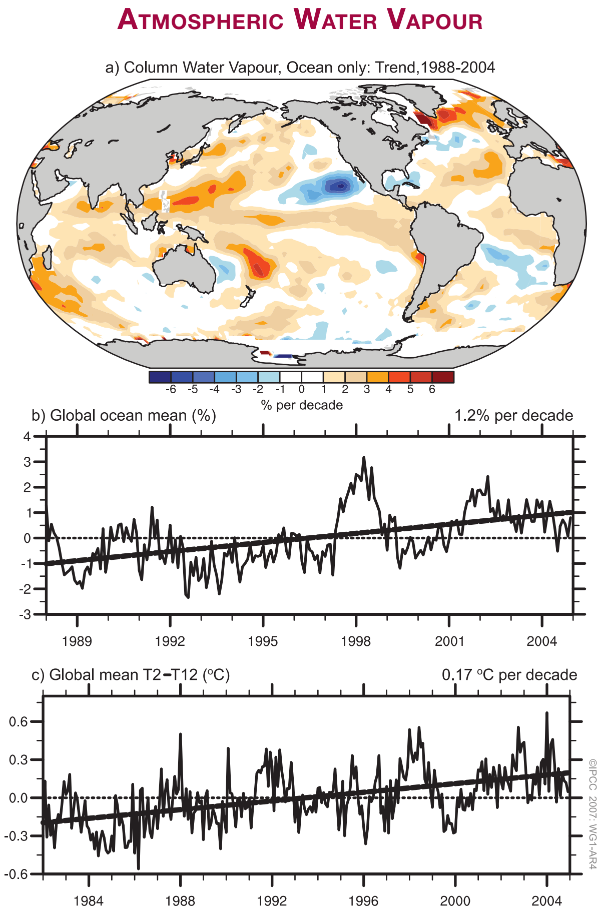


Figure TS.8. *(a) Linear trends in precipitable water (total column water vapour) over the period 1988 to 2004 (% per decade) and (b) the monthly time series of anomalies, relative to the period shown, over the global ocean with linear trend. (c) The global mean (80°N to 80°S) radiative signature of upper-tropospheric moistening is given by monthly time series of combinations of satellite brightness temperature anomalies (°C), relative to the period 1982 to 2004, with the dashed line showing the linear trend of the key brightness temperature in °C per decade. {3.4, Figures 3.20 and 3.21}*

TS.3.1.3 Changes in the Water Cycle: Water Vapour, Clouds, Precipitation and Tropical Storms

Tropospheric water vapour is increasing (Figure TS.8). Surface specific humidity has generally increased since 1976 in close association with higher temperatures over both land and ocean. Total column water vapour has increased over the global oceans by 1.2 ± 0.3% per decade (95% confidence limits) from 1988 to 2004. The observed regional changes are consistent in pattern and amount with the changes in SST and the assumption of a near-constant relative humidity increase in water vapour mixing ratio. The additional atmospheric water vapour implies increased moisture availability for precipitation. {3.4}

Upper-tropospheric water vapour is also increasing. Due to instrumental limitations, it is difficult to assess long-term changes in water vapour in the upper troposphere, where it is of radiative importance. However, the available data now show evidence for global increases in upper-tropospheric specific humidity over the past two decades (Figure TS.8). These observations are consistent with the observed increase in temperatures and represent an important advance since the TAR. {3.4}

Cloud changes are dominated by ENSO. Widespread (but not ubiquitous) decreases in continental DTR have coincided with increases in cloud amounts. Surface and satellite observations disagree on changes in total and low-level cloud changes over the ocean. However, radiation changes at the top of the atmosphere from the 1980s to 1990s (possibly related in part to the ENSO phenomenon) appear to be associated with reductions in tropical upper-level cloud cover, and are consistent with changes in the energy budget and in observed ocean heat content. {3.4}

'Global dimming' is not global in extent and it has not continued after 1990. Reported decreases in solar radiation at the Earth's surface from 1970 to 1990 have an urban bias. Further, there have been increases since about 1990. An increasing aerosol load due to human activities decreases regional air quality and the amount of solar radiation reaching the Earth's surface. In some areas, such as Eastern Europe, recent observations of a reversal in the sign of this effect link changes in solar radiation to concurrent air quality improvements. {3.4}

Long-term trends in precipitation amounts from 1900 to 2005 have been observed in many large regions (Figure TS.9). Significantly increased precipitation has been observed in the eastern parts of North and South America, northern Europe and northern and central Asia. Drying has been observed in the Sahel, the Mediterranean, southern Africa and parts of southern Asia. Precipitation is highly variable spatially and temporally, and robust long-term trends have not been established for other large regions.[5] {3.3}

Substantial increases in heavy precipitation events have been observed. It is *likely* that there have been increases in the number of heavy precipitation events (e.g., above the 95th percentile) in many land regions since about 1950, even in those regions where there has been a reduction in total precipitation amount. Increases have also been reported for rarer precipitation events (1 in 50 year return period), but only a few regions have sufficient data to assess such trends reliably (see Figure TS.10). {3.8}

There is observational evidence for an increase of intense tropical cyclone activity in the North Atlantic since about 1970, correlated with increases in tropical SSTs. There are also suggestions of increased intense tropical cyclone activity in some other regions where concerns over data quality are greater. Multi-decadal variability and the quality of the tropical cyclone records prior to routine satellite observations in about 1970 complicate the detection of long-term trends in tropical cyclone activity and there is no clear trend in the annual numbers of tropical cyclones. Estimates of the potential destructiveness of tropical cyclones suggest a substantial upward trend since the mid-1970s, with a trend towards longer lifetimes and greater intensity. Trends are also apparent in SST, a critical variable known to influence

Global Mean Precipitation

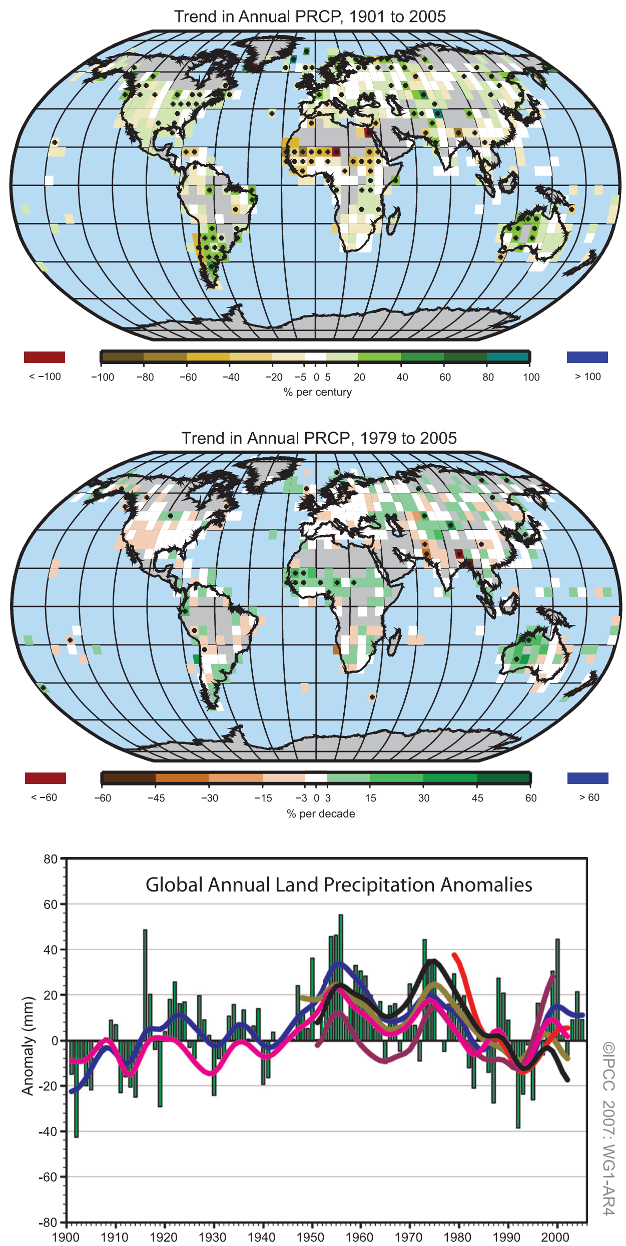

Figure TS.9. *(Top) Distribution of linear trends of annual land precipitation amounts over the period 1901 to 2005 (% per century) and (middle) 1979 to 2005 (% per decade). Areas in grey have insufficient data to produce reliable trends. The percentage is based on the 1961 to 1990 period. (Bottom) Time series of annual global land precipitation anomalies with respect to the 1961 to 1990 base period for 1900 to 2005. The smooth curves show decadal variations (see Appendix 3.A) for different data sets. {3.3, Figures 3.12 and 3.13}*

[5] The assessed regions are those considered in the regional projections chapter of the TAR and in Chapter 11 of this report.

Annual Precipitation Trends

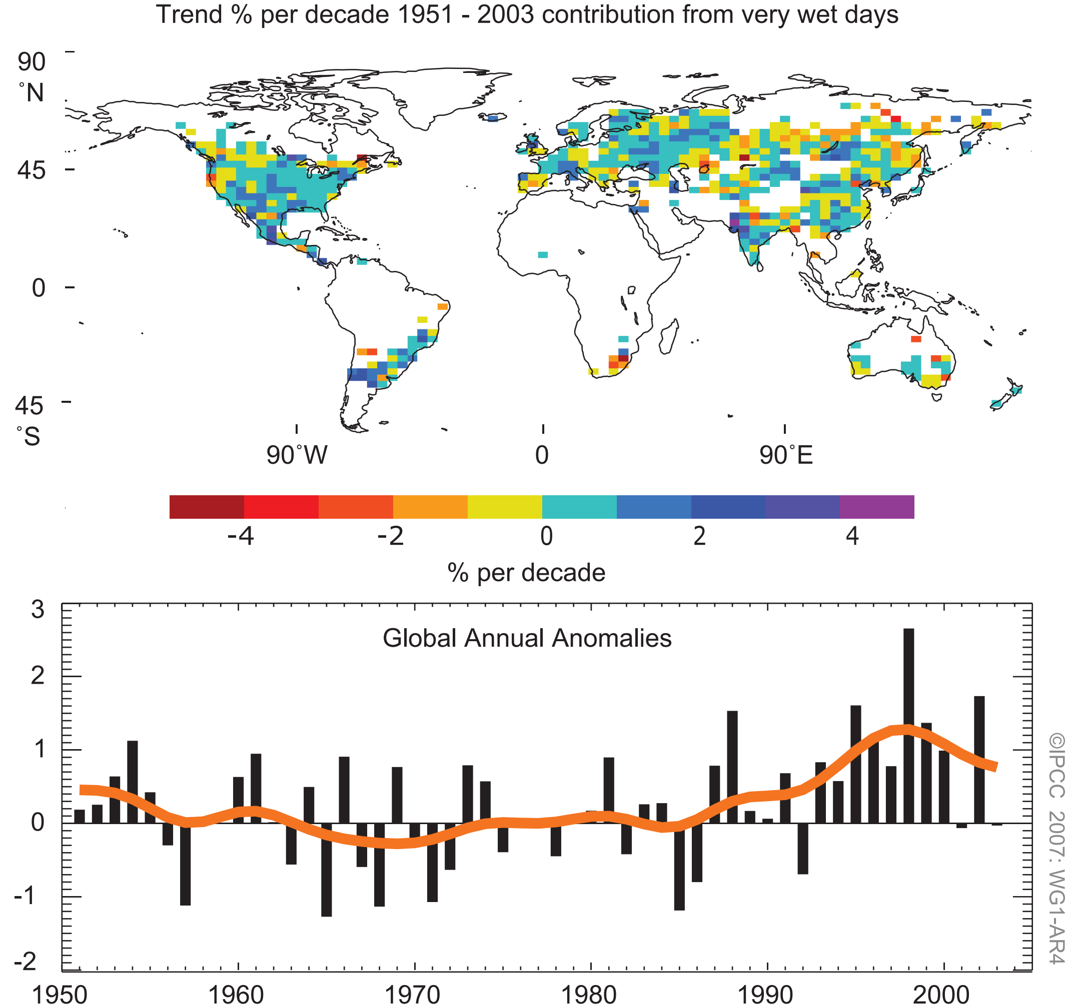

Figure TS.10. *(Top) Observed trends (% per decade) over the period 1951 to 2003 in the contribution to total annual precipitation from very wet days (i.e., corresponding to the 95th percentile and above). White land areas have insufficient data for trend determination. (Bottom) Anomalies (%) of the global (regions with data shown in top panel) annual time series of very wet days (with respect to 1961–1990) defined as the percentage change from the base period average (22.5%). The smooth orange curve shows decadal variations (see Appendix 3.A). {Figure 3.39}*

Annual Sea-Surface Temperature Anomalies

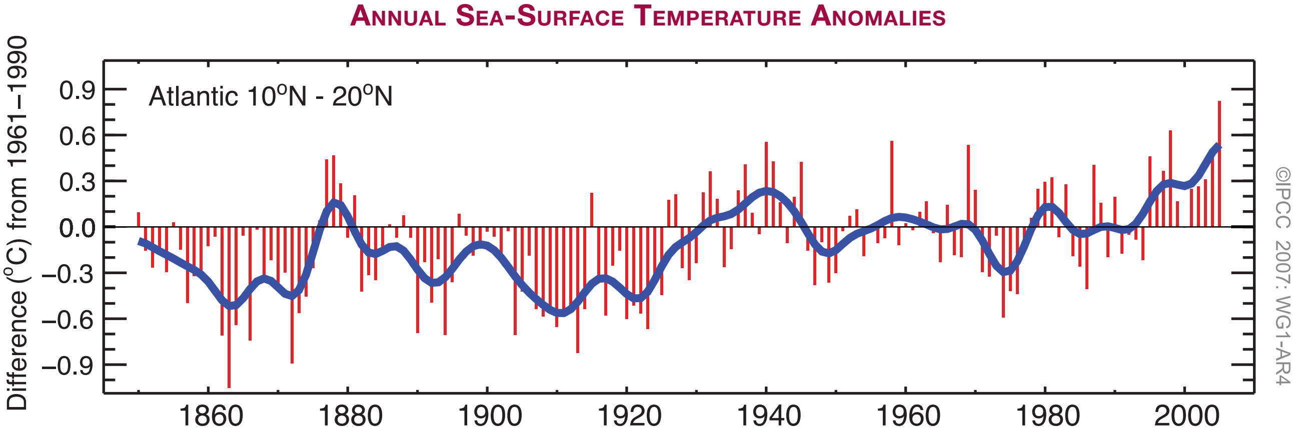

Figure TS.11. *Tropical Atlantic (10°N–20°N) sea surface temperature annual anomalies (°C) in the region of Atlantic hurricane formation, relative to the 1961 to 1990 mean. {Figure 3.33}* tropical cyclone development (see Figure TS.11). Variations in the total numbers of tropical cyclones result from ENSO and decadal variability, which also lead to a redistribution of tropical storm numbers and tracks. The numbers of hurricanes in the North Atlantic have been above normal (based on 1981–2000) in nine of the years from 1995 to 2005. {3.8}

More intense and longer droughts have been observed over wider areas, particularly in the tropics and subtropics since the 1970s. While there are many different measures of drought, many studies use precipitation changes together with temperature.[6] Increased drying due to higher temperatures and decreased land precipitation have contributed to these changes. {3.3}

TS.3.2 Changes in the Cryosphere: Instrumental Record

Currently, ice permanently covers 10% of the land surface, with only a tiny fraction occurring outside Antarctica and Greenland. Ice also covers approximately 7% of the oceans in the annual mean. In midwinter, snow covers approximately 49% of the land surface in the NH. An important property of snow and ice is its high surface albedo. Because up to 90% of the incident solar radiation is reflected by snow and ice surfaces, while only about 10% is reflected by the open ocean or forested lands, changes in snow and ice cover are important feedback mechanisms in climate change. In addition, snow and ice are effective insulators. Seasonally frozen ground is more extensive than snow cover, and its presence is important for energy and moisture fluxes. Therefore, frozen surfaces play important roles in energy and climate processes. {4.1}

The cryosphere stores about 75% of the world's freshwater. At a regional scale, variations in mountain snowpack, glaciers and small ice caps play a crucial role in freshwater availability. Since the change from ice to liquid water occurs at specific temperatures, ice is a component of the climate system that could be subject to abrupt change following sufficient warming. Observations and analyses of changes in ice have expanded and improved since the TAR, including shrinkage of mountain glacier volume, decreases in snow cover, changes in permafrost and frozen ground, reductions in arctic sea ice extent, coastal thinning of the Greenland Ice Sheet exceeding inland thickening from increased snowfall, and reductions in seasonally frozen ground and river and lake ice cover. These allow an improved understanding of how the cryosphere is changing, including its contributions to recent changes in sea level. The periods from 1961 to the present and from 1993 to the present are a focus of this report, due to the availability of directly measured glacier mass balance data and altimetry observations of the ice sheets, respectively. {4.1}

Snow cover has decreased in most regions, especially in spring. Northern Hemisphere snow cover observed by satellite over the 1966 to 2005 period decreased in every month except November and December, with a stepwise drop of 5% in the annual mean in the late 1980s (see Figure TS.12). In the SH, the few long records or proxies mostly show either decreases or no changes in the past 40 years or more. Northern Hemisphere April snow cover extent is strongly correlated with 40°N to 60°N April temperature, reflecting the feedback between snow and temperature. {4.2}

Decreases in snowpack have been documented in several regions worldwide based upon annual time series of mountain snow water equivalent and snow depth. Mountain snow can be sensitive to small changes in temperature, particularly in temperate climatic zones where the transition from rain to snow is generally closely associated with the altitude of the freezing level. Declines in mountain snowpack in western North America and in the Swiss Alps are largest at lower, warmer elevations. Mountain snow water equivalent has declined since 1950 at 75% of the stations monitored in western North America. Mountain snow depth has also declined in the Alps and in southeastern Australia. Direct observations of snow depth are too limited to determine changes in the Andes, but temperature measurements suggest that the altitude where snow occurs (above the snow line) has probably risen in mountainous regions of South America. {4.2}

Permafrost and seasonally frozen ground in most regions display large changes in recent decades. Changes in permafrost conditions can affect river runoff, water supply, carbon exchange and landscape stability, and can cause damage to infrastructure. Temperature increases at the top of the permafrost layer of up to 3°C since the 1980s have been reported. Permafrost warming has also been observed with variable magnitude in the Canadian Arctic, Siberia, the Tibetan Plateau and Europe. The permafrost base is thawing at a rate ranging from 0.04 m yr^{-1} in Alaska to 0.02 m yr^{-1} on the Tibetan Plateau. {4.7}

The maximum area covered by seasonally frozen ground decreased by about 7% in the NH over the

[6] Precipitation and temperature are combined in the Palmer Drought Severity Index (PDSI), considered in this report as one measure of drought. The PDSI does not include variables such as wind speed, solar radiation, cloudiness and water vapour but is a superior measure to precipitation alone.

Box TS.3: Ice Sheet Dynamics and Stability

Ice sheets are thick, broad masses of ice formed mainly from compaction of snow. They spread under their own weight, transferring mass towards their margins where it is lost primarily by runoff of surface melt water or by calving of icebergs into marginal seas or lakes. Ice sheets flow by deformation within the ice or melt water-lubricated sliding over materials beneath. Rapid basal motion requires that the basal temperature be raised to the melting point by heat from the Earth's interior, delivered by melt water transport, or from the 'friction' of ice motion. Sliding velocities under a given gravitational stress can differ by several orders of magnitude, depending on the presence or absence of deformable sediment, the roughness of the substrate and the supply and distribution of water. Basal conditions are generally poorly characterised, introducing important uncertainties to the understanding of ice sheet stability. {4.6}

Ice flow is often channelled into fast-moving ice streams (that flow between slower-moving ice walls) or outlet glaciers (with rock walls). Enhanced flow in ice streams arises either from higher gravitational stress linked to thicker ice in bedrock troughs, or from increased basal lubrication. {4.6}

Ice discharged across the coast often remains attached to the ice sheet to become a floating ice shelf. An ice shelf moves forward, spreading and thinning under its own weight, and fed by snowfall on its surface and ice input from the ice sheet. Friction at ice shelf sides and over local shoals slows the flow of the ice shelf and thus the discharge from the ice sheet. An ice shelf loses mass by calving icebergs from the front and by basal melting into the ocean cavity beneath. Studies suggest an ocean warming of 1°C could increase ice shelf basal melt by 10 m yr^{-1}, but inadequate knowledge of the largely inaccessible ice shelf cavities restricts the accuracy of such estimates. {4.6}

The palaeo-record of previous ice ages indicates that ice sheets shrink in response to warming and grow in response to cooling, and that shrinkage can be far faster than growth. The volumes of the Greenland and Antarctic Ice Sheets are equivalent to approximately 7 m and 57 m of sea level rise, respectively. Palaeoclimatic data indicate that substantial melting of one or both ice sheets has likely occurred in the past. However, ice core data show that neither ice sheet was completely removed during warm periods of at least the past million years. Ice sheets can respond to environmental forcing over very long time scales, implying that commitments to future changes may result from current warming. For example, a surface warming may take more than 10,000 years to penetrate to the bed and change temperatures there. Ice velocity over most of an ice sheet changes slowly in response to changes in the ice sheet shape or surface temperature, but large velocity changes may occur rapidly in ice streams and outlet glaciers in response to changing basal conditions, penetration of surface melt water to the bed or changes in the ice shelves into which they flow. {4.6, 6.4}

Models currently configured for long integrations remain most reliable in their treatment of surface accumulation and ablation, as for the TAR, but do not include full treatments of ice dynamics; thus, analyses of past changes or future projections using such models may underestimate ice flow contributions to sea level rise, but the magnitude of such an effect is unknown. {8.2}

latter half of the 20th century, with a decrease in spring of up to 15%. Its maximum depth has decreased by about 0.3 m in Eurasia since the mid-20th century. In addition, maximum seasonal thaw depth increased by about 0.2 m in the Russian Arctic from 1956 to 1990. {4.7}

On average, the general trend in NH river and lake ice over the past 150 years indicates that the freeze-up date has become later at an average rate of 5.8 ± 1.9 days per century, while the breakup date has occurred earlier, at a rate of 6.5 ± 1.4 days per century. However, considerable spatial variability has also been observed, with some regions showing trends of opposite sign. {4.3}

Annual average arctic sea ice extent has shrunk by about 2.7 ± 0.6% per decade since 1978 based upon satellite observations (see Figure TS.13). The decline in summer extent is larger than in winter extent, with the summer minimum declining at a rate of about 7.4 ± 2.4% per decade. Other data indicate that the summer decline began around 1970. Similar observations in the Antarctic reveal larger interannual variability but no consistent trends during the period of satellite observations. In contrast to changes in continental ice such as ice sheets and glaciers, changes in sea ice do not directly contribute to sea level change (because this ice is already floating), but can contribute to salinity changes through input of freshwater. {4.4}

During the 20th century, glaciers and ice caps have experienced widespread mass losses and have contributed to sea level rise. Mass loss of glaciers and ice caps (excluding those around the ice sheets of Greenland and Antarctica) is estimated to be 0.50 ± 0.18 mm yr^{-1} in sea level equivalent (SLE) between 1961 and 2003, and 0.77 ± 0.22 mm yr^{-1} SLE between 1991 and 2003. The late 20th-century glacier wastage *likely* has been a response to post-1970 warming. {4.5}

Recent observations show evidence for rapid changes in ice flow in some regions, contributing to sea level rise and suggesting that the dynamics of ice

motion may be a key factor in future responses of ice shelves, coastal glaciers and ice sheets to climate change. Thinning or loss of ice shelves in some near-coastal regions of Greenland, the Antarctic Peninsula and West Antarctica has been associated with accelerated flow of nearby glaciers and ice streams, suggesting that ice shelves (including short ice shelves of kilometres or tens of kilometres in length) could play a larger role in stabilising or restraining ice motion than previously thought. Both oceanic and atmospheric temperatures appear to contribute to the observed changes. Large summer warming in the Antarctic Peninsula region *very likely* played a role in the subsequent rapid breakup of the Larsen B Ice Shelf in 2002 by increasing summer melt water, which drained into crevasses and wedged them open. Models do not accurately capture all of the physical processes that appear to be involved in observed iceberg calving (as in the breakup of Larsen B). {4.6}

Changes in Snow Cover

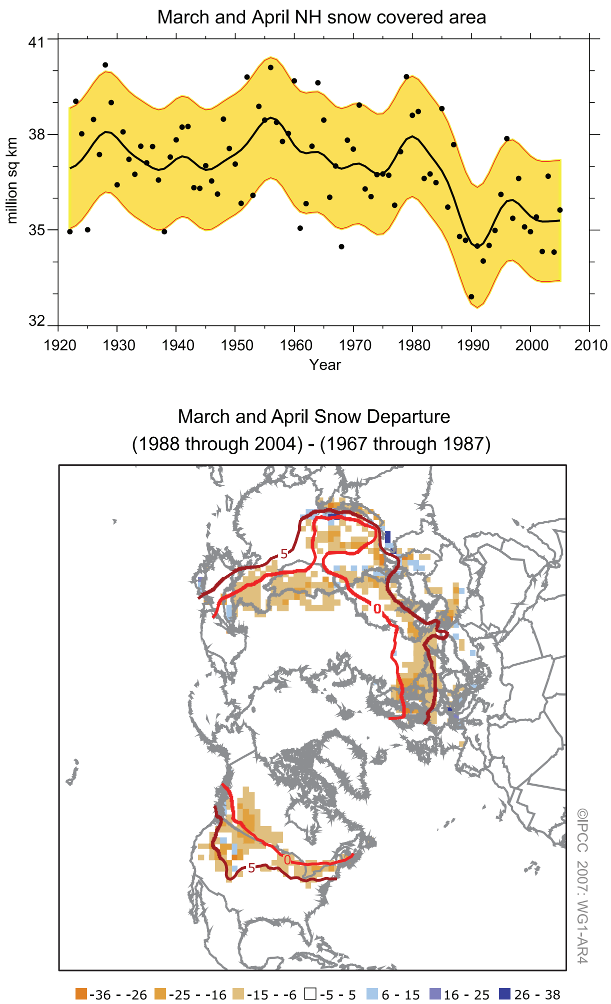

Figure TS.12. *(Top) Northern Hemisphere March-April snow-covered area from a station-derived snow cover index (prior to 1972) and from satellite data (during and after 1972). The smooth curve shows decadal variations (see Appendix 3.A) with the 5 to 95% data range shaded in yellow. (Bottom) Differences in the distribution of March-April snow cover between earlier (1967–1987) and later (1988–2004) portions of the satellite era (expressed in percent coverage). Tan colours show areas where snow cover has declined. Red curves show the 0°C and 5°C isotherms averaged for March-April 1967 to 2004, from the Climatic Research Unit (CRU) gridded land surface temperature version 2 (CRUTEM2v) data. The greatest decline generally tracks the 0°C and 5°C isotherms, reflecting the strong feedback between snow and temperature. {Figures 4.2, 4.3}*

Changes in Sea Ice Extent

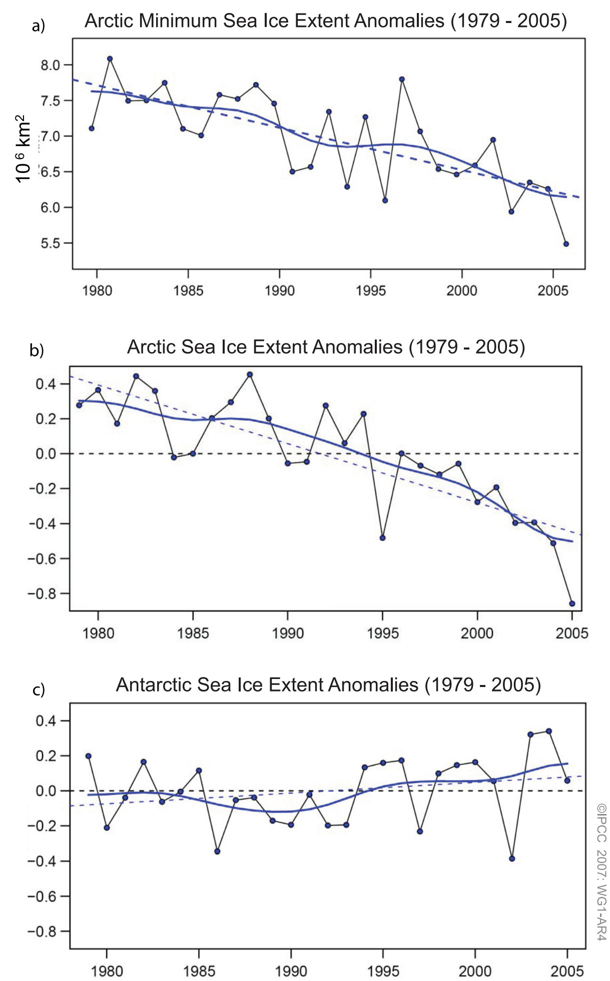

Figure TS.13. *(a) Arctic minimum sea ice extent; (b) arctic sea ice extent anomalies; and (c) antarctic sea ice extent anomalies all for the period 1979 to 2005. Symbols indicate annual values while the smooth blue curves show decadal variations (see Appendix 3.A). The dashed lines indicate the linear trends. (a) Results show a linear trend of –60 ± 20 x 10^3 km^2 yr^{-1}, or approximately -7.4% per decade. (b) The linear trend is –33 ± 7.4 x 10^3 km^2 yr^{-1} (equivalent to approximately –2.7% per decade) and is significant at the 95% confidence level. (c) Antarctic results show a small positive trend of 5.6 ± 9.2 x 10^3 km^2 yr^{-1}, which is not statistically significant. {Figures 4.8 and 4.9}*

The Greenland and Antarctic Ice Sheets taken together have *very likely* contributed to the sea level rise of the past decade. It is *very likely* that the Greenland Ice Sheet shrunk from 1993 to 2003, with thickening in central regions more than offset by increased melting in coastal regions. Whether the ice sheets have been growing or shrinking over time scales of longer than a decade is not well established from observations. Lack of agreement between techniques and the small number of estimates preclude assignment of best estimates or statistically rigorous error bounds for changes in ice sheet mass balances. However, acceleration of outlet glaciers drains ice from the interior and has been observed in both ice sheets (see Figure TS.14). Assessment of the data and techniques suggests a mass balance for the Greenland Ice Sheet of –50 to –100 Gt yr^{-1} (shrinkage contributing to raising global sea level by 0.14 to 0.28 mm yr^{-1}) during 1993 to 2003, with even larger losses in 2005. There are greater uncertainties for earlier time periods and for Antarctica. The estimated range in mass balance for the Greenland Ice Sheet over the period 1961 to 2003 is between growth of 25 Gt yr^{-1} and shrinkage by 60 Gt yr^{-1} (–0.07 to +0.17 mm yr^{-1} SLE). Assessment of all the data yields an estimate for the overall Antarctic Ice Sheet mass balance ranging from growth of 100 Gt yr^{-1} to shrinkage of 200 Gt yr^{-1} (–0.27 to +0.56 mm yr^{-1} SLE) from 1961 to 2003, and from +50 to –200 Gt yr^{-1} (–0.14 to +0.55 mm yr^{-1} SLE) from 1993 to 2003. The recent changes in ice flow are *likely* to be sufficient to explain much or all of the estimated antarctic mass imbalance, with recent changes in ice flow, snowfall and melt water runoff sufficient to explain the mass imbalance of Greenland. {4.6, 4.8}

Rates of Observed Surface Elevation Change

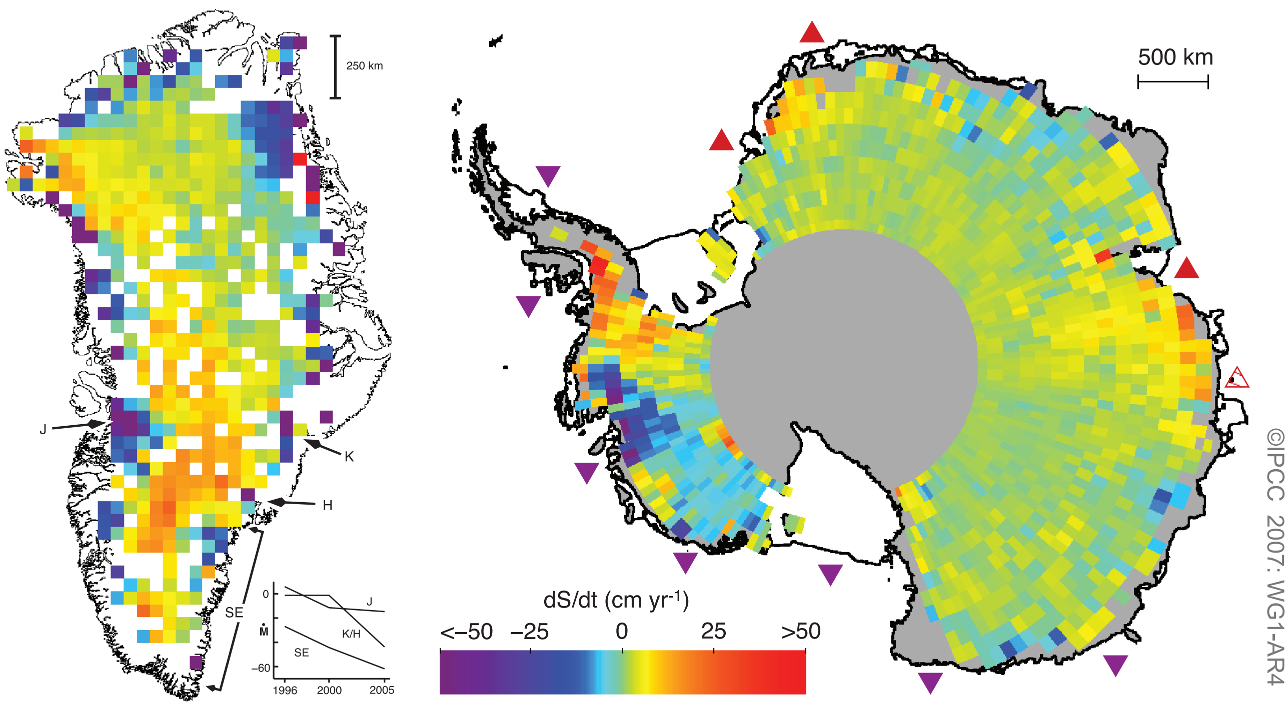

Figure TS.14. *Rates of observed recent surface elevation change for Greenland (left; 1989–2005) and Antarctica (right; 1992–2005). Red hues indicate a rising surface and blue hues a falling surface, which typically indicate an increase or loss in ice mass at a site, although changes over time in bedrock elevation and in near-surface density can be important. For Greenland, the rapidly thinning outlet glaciers Jakobshavn (J), Kangerdlugssuaq (K), Helheim (H) and areas along the southeast coast (SE) are shown, together with their estimated mass balance vs. time (with K and H combined, in Gt yr^{-1}, with negative values indicating loss of mass from the ice sheet to the ocean). For Antarctica, ice shelves estimated to be thickening or thinning by more than 30 cm yr^{-1} are shown by point-down purple triangles (thinning) and point-up red triangles (thickening) plotted just seaward of the relevant ice shelves. {Figures 4.17 and 4.19}*

TS.3.3 Changes in the Ocean: Instrumental Record

The ocean plays an important role in climate and climate change. The ocean is influenced by mass, energy and momentum exchanges with the atmosphere. Its heat capacity is about 1000 times larger than that of the atmosphere and the ocean's net heat uptake is therefore many times greater than that of the atmosphere (see Figure TS.15). Global observations of the heat taken up by the ocean can now be shown to be a definitive test of changes in the global energy budget. Changes in the amount of energy taken up by the upper layers of the ocean also play a crucial role for climate variations on seasonal to interannual time scales, such as El Niño. Changes in the transport of heat and SSTs have important effects upon many regional climates worldwide. Life in the sea is dependent on the biogeochemical status of the ocean and is affected by changes in its physical state and circulation. Changes in ocean biogeochemistry can also feed back into the climate system, for example, through changes in uptake or release of radiatively active gases such as CO_2. {5.1, 7.3}

Energy Content in the Climate System

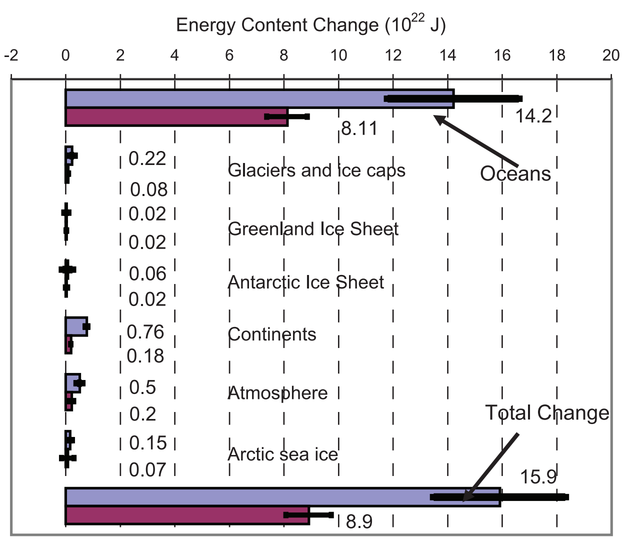

Figure TS.15. *Energy content changes in different components of the Earth system for two periods (1961–2003 and 1993–2003). Blue bars are for 1961 to 2003; burgundy bars are for 1993 to 2003. Positive energy content change means an increase in stored energy (i.e., heat content in oceans, latent heat from reduced ice or sea ice volumes, heat content in the continents excluding latent heat from permafrost changes, and latent and sensible heat and potential and kinetic energy in the atmosphere). All error estimates are 90% confidence intervals. No estimate of confidence is available for the continental heat gain. Some of the results have been scaled from published results for the two respective periods. {Figure 5.4}*

Global mean sea level variations are driven in part by changes in density, through thermal expansion or contraction of the ocean's volume. Local changes in sea level also have a density-related component due to temperature and salinity changes. In addition, exchange of water between oceans and other reservoirs (e.g., ice sheets, mountain glaciers, land water reservoirs and the atmosphere) can change the ocean's mass and hence contribute to changes in sea level. Sea level change is not geographically uniform because processes such as ocean circulation changes are not uniform across the globe (see Box TS.4). {5.5}

Oceanic variables can be useful for climate change detection, in particular temperature and salinity changes below the surface mixed layer where the variability is smaller and signal-to-noise ratio is higher. Observations analysed since the TAR have provided new evidence for changes in global ocean heat content and salinity, sea level, thermal expansion contributions to sea level rise, water mass evolution and biogeochemical cycles. {5.5}

TS.3.3.1 Changes in Ocean Heat Content and Circulation

The world ocean has warmed since 1955, accounting over this period for more than 80% of the changes in the energy content of the Earth's climate system. A total of 7.9 million vertical profiles of ocean temperature allows construction of improved global time series (see Figure TS.16). Analyses of the global oceanic heat budget have been replicated by several independent analysts and are robust to the method used. Data coverage limitations require averaging over decades for the deep ocean and observed decadal variability in the global heat content is not fully understood. However, inadequacies in the distribution of data (particularly coverage in the Southern Ocean and South Pacific) could contribute to the apparent decadal variations in heat content. During the period 1961 to 2003, the 0 to 3000 m ocean layer has taken up about 14.1×10^{22} J, equivalent to an average heating rate of 0.2 W m^{-2} (per unit area of the Earth's surface). During 1993 to 2003, the corresponding rate of warming in the shallower 0 to 700 m ocean layer was higher, about 0.5 ± 0.18 W m^{-2}. Relative to 1961 to 2003, the period 1993 to 2003 had high rates of warming but in 2004 and 2005 there has been some cooling compared to 2003. {5.1–5.3}

Warming is widespread over the upper 700 m of the global ocean. The Atlantic has warmed south of 45°N. The warming is penetrating deeper in the Atlantic Ocean Basin than in the Pacific, Indian and Southern Oceans, due to the

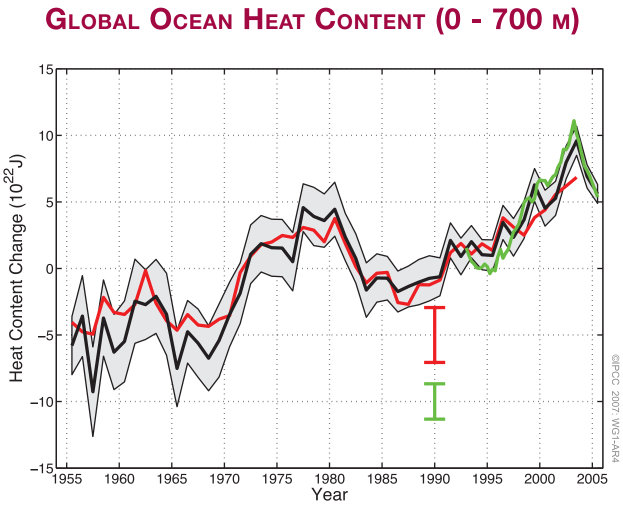

Figure TS.16. *Time series of global ocean heat content (10^{22} J) for the 0 to 700 m layer. The three coloured lines are independent analyses of the oceanographic data. The black and red curves denote the deviation from their 1961 to 1990 average and the shorter green curve denotes the deviation from the average of the black curve for the period 1993 to 2003. The 90% uncertainty range for the black curve is indicated by the grey shading and for the other two curves by the error bars. {Figure 5.1}*

deep overturning circulation cell that occurs in the North Atlantic. The SH deep overturning circulation shows little evidence of change based on available data. However, the upper layers of the Southern Ocean contribute strongly to the overall warming. At least two seas at subtropical latitudes (Mediterranean and Japan/East China Sea) are warming. While the global trend is one of warming, significant decadal variations have been observed in the global time series, and there are large regions where the oceans are cooling. Parts of the North Atlantic, North Pacific and equatorial Pacific have cooled over the last 50 years. The changes in the Pacific Ocean show ENSO-like spatial patterns linked in part to the PDO. {5.2, 5.3}

Parts of the Atlantic meridional overturning circulation exhibit considerable decadal variability, but data do not support a coherent trend in the overturning circulation. {5.3}

TS.3.3.2 Changes in Ocean Biogeochemistry and Salinity

The uptake of anthropogenic carbon since 1750 has led to the ocean becoming more acidic, with an average decrease in surface pH of 0.1 units.[7] Uptake of CO_2 by the ocean changes its chemical equilibrium. Dissolved CO_2 forms a weak acid, so as dissolved CO_2 increases, pH decreases (i.e., the ocean becomes more acidic). The overall pH change is computed from estimates of anthropogenic carbon uptake and simple ocean models. Direct observations of pH at available stations for the last 20 years also show trends of decreasing pH, at a rate of about 0.02 pH units per decade. Decreasing ocean pH decreases the depth below which calcium carbonate dissolves and increases the volume of the ocean that is undersaturated with respect to the minerals aragonite (a meta-stable form of calcium carbonate) and calcite, which are used by marine organisms to build their shells. Decreasing surface ocean pH and rising surface temperatures also act to reduce the ocean buffer capacity for CO_2 and the rate at which the ocean can take up excess atmospheric CO_2. {5.4, 7.3}

The oxygen concentration of the ventilated thermocline (about 100 to 1000 m) decreased in most ocean basins between 1970 and 1995. These changes may reflect a reduced rate of ventilation linked to upper-level warming and/or changes in biological activity. {5.4}

There is now widespread evidence for changes in ocean salinity at gyre and basin scales in the past half century (see Figure TS.17) with the near-surface waters in the more evaporative regions increasing in salinity in almost all ocean basins. These changes in salinity imply changes in the hydrological cycle over the oceans. In the high-latitude regions in both hemispheres, the surface waters show an overall freshening consistent with these regions having greater precipitation, although higher runoff, ice melting, advection and changes in the meridional overturning circulation may also contribute. The subtropical latitudes in both hemispheres are characterised by an increase in salinity in the upper 500 m. The patterns are consistent with a change in the Earth's hydrological cycle, in particular with changes in precipitation and inferred larger water transport in the atmosphere from low latitudes to high latitudes and from the Atlantic to the Pacific. {5.2}

TS.3.3.3 Changes in Sea Level

Over the 1961 to 2003 period, the average rate of global mean sea level rise is estimated from tide gauge data to be 1.8 ± 0.5 mm yr^{-1} (see Figure TS.18). For the purpose of examining the sea level budget, best estimates and 5 to 95% confidence intervals are provided for all land ice contributions. The average

[7] Acidity is a measure of the concentration of H^+ ions and is reported in pH units, where pH = –log(H^+). A pH decrease of 1 unit means a 10-fold increase in the concentration of H^+, or acidity.

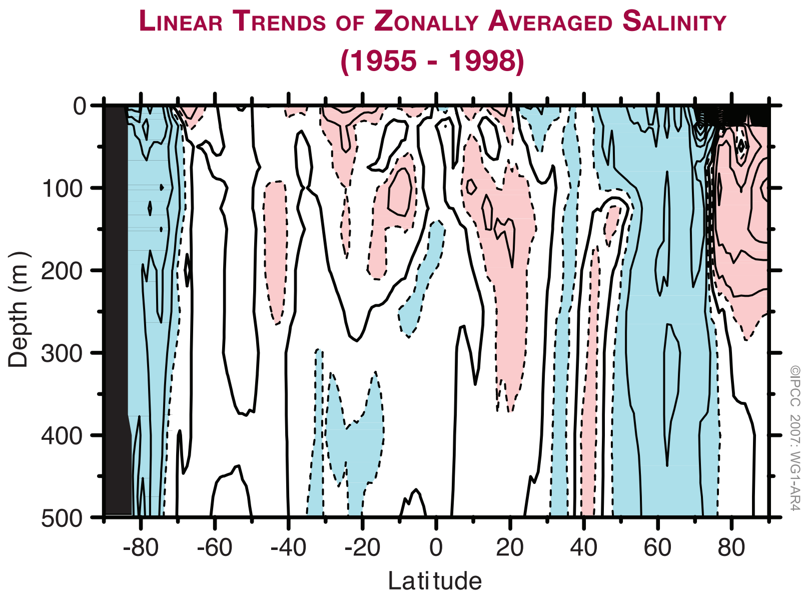

Figure TS.17. *Linear trends (1955–1998) of zonally averaged salinity (Practical Salinity Scale) for the World Ocean. The contour interval is 0.01 per decade and dashed contours are ±0.005 per decade. The dark, solid line is the zero contour. Red shading indicates values equal to or greater than 0.005 per decade and blue shading indicates values equal to or less than –0.005 per decade. {Figure 5.5}*

thermal expansion contribution to sea level rise for this period was 0.42 ± 0.12 mm yr^{-1}, with significant decadal variations, while the contribution from glaciers, ice caps and ice sheets is estimated to have been 0.7 ± 0.5 mm yr^{-1} (see Table TS.3). The sum of these estimated climate-related contributions for about the past four decades thus amounts to 1.1 ± 0.5 mm yr^{-1}, which is less than the best estimate from the tide gauge observations (similar to the discrepancy noted in the TAR). Therefore, the sea level budget for 1961 to 2003 has not been closed satisfactorily. {4.8, 5.5}

The global average rate of sea level rise measured by TOPEX/Poseidon satellite altimetry during 1993 to 2003 is 3.1 ± 0.7 mm yr^{-1}. This observed rate for the recent period is close to the estimated total of 2.8 ± 0.7 mm yr^{-1} for the climate-related contributions due to thermal expansion (1.6 ± 0.5 mm yr^{-1}) and changes in land ice (1.2 ± 0.4 mm yr^{-1}). Hence, the understanding of the budget has improved significantly for this recent period, with the climate contributions constituting the main factors in the sea level budget (which is closed to within known errors). Whether the faster rate for 1993 to 2003 compared to 1961 to 2003 reflects decadal variability or an increase in the longer-term trend is unclear. The tide gauge record indicates that faster rates similar to that observed in 1993 to 2003 have occurred in other decades since 1950. {5.5, 9.5}

There is *high confidence* that the rate of sea level rise accelerated between the mid-19th and the mid-20th centuries based upon tide gauge and geological data. A recent reconstruction of sea level change back to 1870 using the best available tide records provides high confidence that the rate of sea level rise accelerated over the period 1870 to 2000. Geological observations indicate that during the previous 2000 years, sea level change was small, with average rates in the range 0.0 to 0.2 mm yr^{-1}. The use of proxy sea level data from archaeological sources is well established in the Mediterranean and indicates that oscillations in sea level from about AD 1 to AD 1900 did not exceed ±0.25 m. The available evidence indicates that the onset of modern sea level rise started between the mid-19th and mid-20th centuries. {5.5}

Precise satellite measurements since 1993 now provide unambiguous evidence of regional variability of sea level change. In some regions, rates of rise during this period are up to several times the global mean,

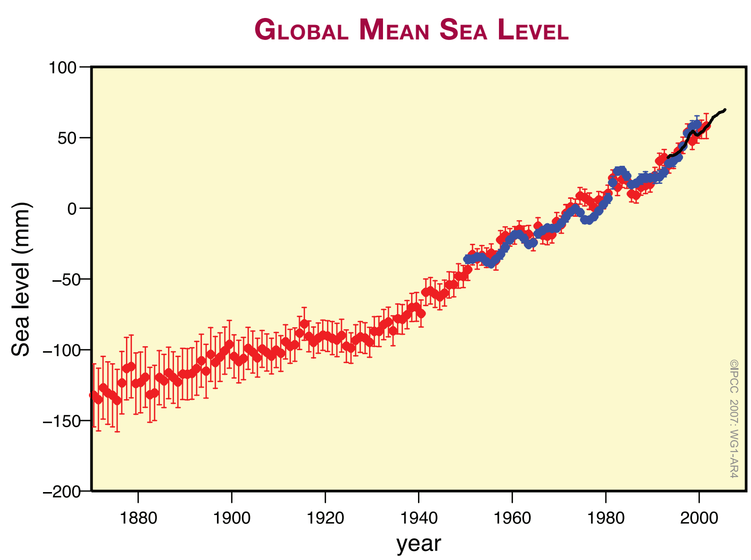

Figure TS.18. *Annual averages of the global mean sea level based on reconstructed sea level fields since 1870 (red), tide gauge measurements since 1950 (blue) and satellite altimetry since 1992 (black). Units are in mm relative to the average for 1961 to 1990. Error bars are 90% confidence intervals. {Figure 5.13}*

Table TS.3. *Contributions to sea level rise based upon observations (left columns) compared to models used in this assessment (right columns; see Section 9.5 and Appendix 10.A for details). Values are presented for 1993 to 2003 and for the last four decades, including observed totals. {Adapted from Tables 5.3 and 9.2}*

	Sea Level Rise (mm yr^{-1})			
	1961–2003		1993–2003	
Sources of Sea Level Rise	**Observed**	**Modelled**	**Observed**	**Modelled**
Thermal expansion	0.42 ± 0.12	0.5 ± 0.2	1.6 ± 0.5	1.5 ± 0.7
Glaciers and ice caps	0.50 ± 0.18	0.5 ± 0.2	0.77 ± 0.22	0.7 ± 0.3
Greenland Ice Sheet	0.05 ± 0.12[a]		0.21 ± 0.07[a]

Sum of individual climate contributions to sea level rise	1.1 ± 0.5	1.2 ± 0.5	2.8 ± 0.7	2.6 ± 0.8
Observed total sea level rise	1.8 ± 0.5 (tide gauges)		3.1 ± 0.7 (satellite altimeter)	
Difference (Observed total minus the sum of observed climate contributions)	0.7 ± 0.7		0.3 ± 1.0	

Notes:
[a] prescribed based upon observations (see Section 9.5)

while in other regions sea level is falling. The largest sea level rise since 1992 has taken place in the western Pacific and eastern Indian Oceans (see Figure TS.19). Nearly all of the Atlantic Ocean shows sea level rise during the past decade, while sea level in the eastern Pacific and western Indian Oceans has been falling. These temporal and spatial variations in regional sea level rise are influenced in part by patterns of coupled ocean-atmosphere variability, including ENSO and the NAO. The pattern of observed sea level change since 1992 is similar to the thermal expansion computed from ocean temperature changes, but different from the thermal expansion pattern of the last 50 years, indicating the importance of regional decadal variability. {5.5}

Observations suggest increases in extreme high water at a broad range of sites worldwide since 1975. Longer records are limited in space and under-sampled in time, so a global analysis over the entire 20th century is not feasible. In many locations, the secular changes in extremes were similar to those in mean sea level. At others, changes in atmospheric conditions such as storminess were more important in determining long-term trends. Interannual variability in high water extremes was positively correlated with regional mean sea level, as well as to indices of regional climate such as ENSO in the Pacific and NAO in the Atlantic. {5.5}

Sea Level Change Patterns

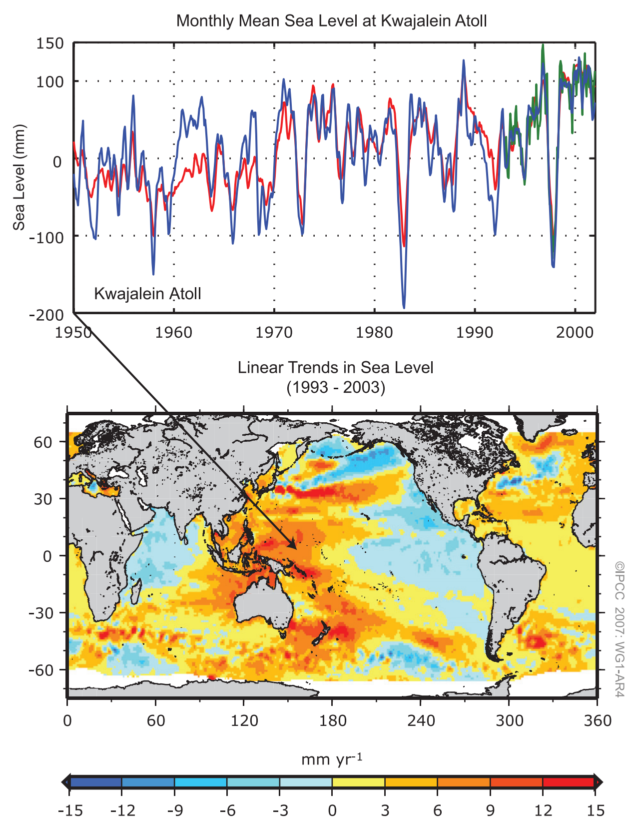

Figure TS.19. *(Top) Monthly mean sea level (mm) curve for 1950 to 2000 at Kwajalein (8°44'N, 167°44'E). The observed sea level (from tide gauge measurements) is in blue, the reconstructed sea level in red and the satellite altimetry record in green. Annual and semiannual signals have been removed from each time series and the tide gauge data have been smoothed. (Bottom) Geographic distribution of short-term linear trends in mean sea level for 1993 to 2003 (mm yr^{-1}) based on TOPEX/Poseidon satellite altimetry. {Figures 5.15 and 5.18}*

Box TS.4: Sea Level

The level of the sea at the shoreline is determined by many factors that operate over a great range of temporal scales: hours to days (tides and weather), years to millennia (climate), and longer. The land itself can rise and fall and such regional land movements need to be accounted for when using tide gauge measurements for evaluating the effect of oceanic climate change on coastal sea level. Coastal tide gauges indicate that global average sea level rose during the 20th century. Since the early 1990s, sea level has also been observed continuously by satellites with near-global coverage. Satellite and tide gauge data agree at a wide range of spatial scales and show that global average sea level has continued to rise during this period. Sea level changes show geographical variation because of several factors, including the distributions of changes in ocean temperature, salinity, winds and ocean circulation. Regional sea level is affected by climate variability on shorter time scales, for instance associated with El Niño and the NAO, leading to regional interannual variations which can be much greater or weaker than the global trend.

Based on ocean temperature observations, the thermal expansion of seawater as it warms has contributed substantially to sea level rise in recent decades. Climate models are consistent with the ocean observations and indicate that thermal expansion is expected to continue to contribute to sea level rise over the next 100 years. Since deep ocean temperatures change only slowly, thermal expansion would continue for many centuries even if atmospheric concentrations of greenhouse gases were stabilised.

Global average sea level also rises or falls when water is transferred from land to ocean or vice versa. Some human activities can contribute to sea level change, especially by the extraction of groundwater and construction of reservoirs. However, the major land store of freshwater is the water frozen in glaciers, ice caps and ice sheets. Sea level was more than 100 m lower during the glacial periods because of the ice sheets covering large parts of the NH continents. The present-day retreat of glaciers and ice caps is making a substantial contribution to sea level rise. This is expected to continue during the next 100 years. Their contribution should decrease in subsequent centuries as this store of freshwater diminishes.

The Greenland and Antarctic Ice Sheets contain much more ice and could make large contributions over many centuries. In recent years the Greenland Ice Sheet has experienced greater melting, which is projected to increase further. In a warmer climate, models suggest that the ice sheets could accumulate more snowfall, tending to lower sea level. However, in recent years any such tendency has probably been outweighed by accelerated ice flow and greater discharge observed in some marginal areas of the ice sheets. The processes of accelerated ice flow are not yet completely understood but could result in overall net sea level rise from ice sheets in the future.

The greatest climate- and weather-related impacts of sea level are due to extremes on time scales of days and hours, associated with tropical cyclones and mid-latitude storms. Low atmospheric pressure and high winds produce large local sea level excursions called 'storm surges', which are especially serious when they coincide with high tide. Changes in the frequency of occurrence of these extreme sea levels are affected both by changes in mean sea level and in the meteorological phenomena causing the extremes. {5.5}

TS.3.4 Consistency Among Observations

In this section, variability and trends within and across different climate variables including the atmosphere, cryosphere and oceans are examined for consistency based upon conceptual understanding of physical relationships between the variables. For example, increases in temperature will enhance the moisture-holding capacity of the atmosphere. Changes in temperature and/or precipitation should be consistent with those evident in glaciers. Consistency between independent observations using different techniques and variables provides a key test of understanding, and hence enhances confidence. {3.9}

Changes in the atmosphere, cryosphere and ocean show unequivocally that the world is warming. {3.2, 3.9, 4.2, 4.4–4.8, 5.2, 5.5}

Both land surface air temperatures and SSTs show warming. In both hemispheres, land regions have warmed at a faster rate than the oceans in the past few decades, consistent with the much greater thermal inertia of the oceans. {3.2}

The warming of the climate is consistent with observed increases in the number of daily warm extremes, reductions in the number of daily cold extremes and reductions in the number of frost days at mid-latitudes. {3.2, 3.8}

Surface air temperature trends since 1979 are now consistent with those at higher altitudes. It is *likely* that there is slightly greater warming in the troposphere than at the surface, and a higher tropopause, consistent with expectations from basic physical processes and observed increases in greenhouse gases together with depletion of stratospheric ozone. {3.4, 9.4}

Changes in temperature are broadly consistent with the observed nearly worldwide shrinkage of the cryosphere. There have been widespread reductions in mountain glacier mass and extent. Changes in climate consistent with warming are also indicated by decreases in snow cover, snow depth, arctic sea ice extent, permafrost thickness and temperature, the extent of seasonally frozen ground and the length of the freeze season of river and lake ice. {3.2, 3.9, 4.2–4.5, 4.7}

Observations of sea level rise since 1993 are consistent with observed changes in ocean heat content and the cryosphere. Sea level rose by 3.1 ± 0.7 mm yr^{-1} from 1993 to 2003, the period of availability of global altimetry measurements. During this time, a near balance was observed between observed total sea level rise and contributions from glacier, ice cap and ice sheet retreat together with increases in ocean heat content and associated ocean expansion. This balance gives increased

Table TS.4. *Recent trends, assessment of human influence on trends, and projections of extreme weather and climate events for which there is evidence of an observed late 20th-century trend. An asterisk in the column headed 'D' indicates that formal detection and attribution studies were used, along with expert judgement, to assess the likelihood of a discernible human influence. Where this is not available, assessments of likelihood of human influence are based on attribution results for changes in the mean of a variable or changes in physically related variables and/or on the qualitative similarity of observed and simulated changes, combined with expert judgement. {3.8, 5.5, 9.7, 11.2–11.9; Tables 3.7, 3.8, 9.4}*

Phenomenon[a] and direction of trend	Likelihood that trend occurred in late 20th century (typically post-1960)	Likelihood of a human contribution to observed trend	D	Likelihood of future trend based on projections for 21st century using SRES[b] scenarios
Warmer and fewer cold days and nights over most land areas	*Very likely*[c]	*Likely*[e]	*	*Virtually certain*[e]
Warmer and more frequent hot days and nights over most land areas	*Very likely*[d]	*Likely* (nights)[e]	*	*Virtually certain*[e]
Warm spells / heat waves: Frequency increases over most land areas	*Likely*	*More likely than not*		*Very likely*
Heavy precipitation events. Frequency (or proportion of total rainfall from heavy falls) increases over most areas	*Likely*	*More likely than not*		*Very likely*
Area affected by droughts increases	*Likely* in many regions since 1970s	*More likely than not*	*	*Likely*
Intense tropical cyclone activity increases	*Likely* in some regions since 1970	*More likely than not*		*Likely*
Increased incidence of extreme high sea level (excludes tsunamis)[f]	*Likely*	*More likely than not*[g]		*Likely*[h]

Notes:
[a] See Table 3.7 for further details regarding definitions.
[b] SRES refers to the IPCC Special Report on Emission Scenarios. The SRES scenario families and illustrative cases are summarised in a box at the end of the Summary for Policymakers.
[c] Decreased frequency of cold days and nights (coldest 10%)
[d] Increased frequency of hot days and nights (hottest 10%)
[e] Warming of the most extreme days/nights each year
[f] Extreme high sea level depends on average sea level and on regional weather systems. It is defined here as the highest 1% of hourly values of observed sea level at a station for a given reference period.
[g] Changes in observed extreme high sea level closely follow the changes in average sea level {5.5.2.6}. It is *very likely* that anthropogenic activity contributed to a rise in average sea level. {9.5.2}
[h] In all scenarios, the projected global average sea level at 2100 is higher than in the reference period {10.6}. The effect of changes in regional weather systems on sea level extremes has not been assessed.

confidence that the observed sea level rise is a strong indicator of warming. However, the sea level budget is not balanced for the longer period 1961 to 2003. {5.5, 3.9}

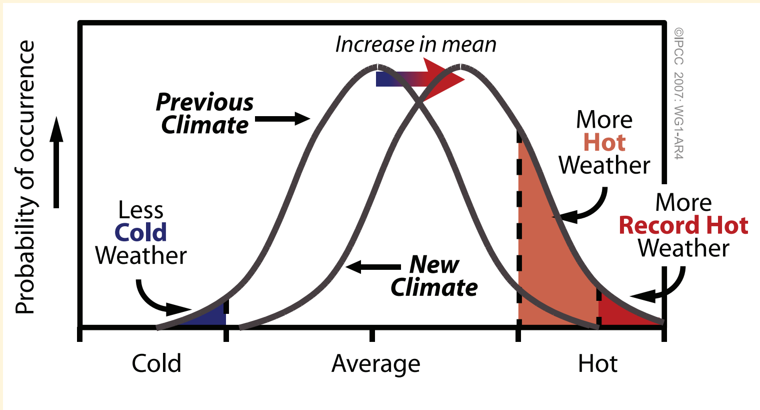
Observations are consistent with physical understanding regarding the expected linkage between water vapour and temperature, and with intensification of precipitation events in a warmer world. Column and upper-tropospheric water vapour have increased, providing important support for the hypothesis of simple physical models that specific humidity increases in a warming world and represents an important positive feedback to climate change. Consistent with rising amounts of water vapour in the atmosphere, there are widespread increases in the numbers of heavy precipitation events and increased likelihood of flooding events in many land regions, even those where there has been a reduction in total precipitation. Observations of changes in ocean salinity independently support the view

Box TS.5: Extreme Weather Events

People affected by an extreme weather event (e.g., the extremely hot summer in Europe in 2003, or the heavy rainfall in Mumbai, India in July 2005) often ask whether human influences on the climate are responsible for the event. A wide range of extreme weather events is expected in most regions even with an unchanging climate, so it is difficult to attribute any individual event to a change in the climate. In most regions, instrumental records of variability typically extend only over about 150 years, so there is limited information to characterise how extreme rare climatic events could be. Further, several factors usually need to combine to produce an extreme event, so linking a particular extreme event to a single, specific cause is problematic. In some cases, it may be possible to estimate the anthropogenic contribution to such changes in the probability of occurrence of extremes.

However, simple statistical reasoning indicates that substantial changes in the frequency of extreme events (and in the maximum feasible extreme, e.g., the maximum possible 24-hour rainfall at a specific location) can result from a relatively small shift of the distribution of a weather or climate variable.

Extremes are the infrequent events at the high and low end of the range of values of a particular variable. The probability of occurrence of values in this range is called a probability distribution function (PDF) that for some variables is shaped similarly to a 'Normal' or 'Gaussian' curve (the familiar 'bell' curve). Box TS.5, Figure 1 shows a schematic of a such a PDF and illustrates the effect a small shift (corresponding to a small change in the average or centre of the distribution) can have on the frequency of extremes at either end of the distribution. An increase in the frequency of one extreme (e.g., the number of hot days) will often be accompanied by a decline in the opposite extreme (in this case the number of cold days such as frosts). Changes in the variability or shape of the distribution can complicate this simple picture.



Box TS.5, Figure 1. *Schematic showing the effect on extreme temperatures when the mean temperature increases, for a normal temperature distribution.*

The IPCC Second Assessment Report noted that data and analyses of extremes related to climate change were sparse. By the time of the TAR, improved monitoring and data for changes in extremes was available, and climate models were being analysed to provide projections of extremes. Since the TAR, the observational basis of analyses of extremes has increased substantially, so that some extremes have now been examined over most land areas (e.g., daily temperature and rainfall extremes). More models have been used in the simulation and projection of extremes, and multiple integrations of models with different starting conditions (ensembles) now provide more robust information about PDFs and extremes. Since the TAR, some climate change detection and attribution studies focussed on changes in the global statistics of extremes have become available (Table TS.4). For some extremes (e.g., tropical cyclone intensity), there are still data concerns and/or inadequate models. Some assessments still rely on simple reasoning about how extremes might be expected to change with global warming (e.g., warming could be expected to lead to more heat waves). Others rely on qualitative similarity between observed and simulated changes. The assessed likelihood of anthropogenic contributions to trends is lower for variables where the assessment is based on indirect evidence.

that the Earth's hydrologic cycle has changed, in a manner consistent with observations showing greater precipitation and river runoff outside the tropics and subtropics, and increased transfer of freshwater from the ocean to the atmosphere at lower latitudes. {3.3, 3.4, 3.9, 5.2}

Although precipitation has increased in many areas of the globe, the area under drought has also increased. Drought duration and intensity has also increased. While regional droughts have occurred in the past, the widespread spatial extent of current droughts is broadly consistent with expected changes in the hydrologic cycle under warming. Water vapour increases with increasing global temperature, due to increased evaporation where surface moisture is available, and this tends to increase precipitation. However, increased continental temperatures are expected to lead to greater evaporation and drying, which is particularly important in dry regions where surface moisture is limited. Changes in snowpack, snow cover and in atmospheric circulation patterns and storm tracks can also reduce available seasonal moisture, and contribute to droughts. Changes in SSTs and associated changes in the atmospheric circulation and precipitation have contributed to changes in drought, particularly at low latitudes. The result is that drought has become more common, especially in the tropics and subtropics, since the 1970s. In Australia and Europe, direct links to global warming have been inferred through the extremes in high temperatures and heat waves accompanying recent droughts. {3.3, 3.8, 9.5}

TS.3.5 A Palaeoclimatic Perspective

Palaeoclimatic studies make use of measurements of past change derived from borehole temperatures, ocean sediment pore-water change and glacier extent changes, as well as proxy measurements involving the changes in chemical, physical and biological parameters that reflect past changes in the environment where the proxy grew or existed. Palaeoclimatic studies rely on multiple proxies so that results can be cross-verified and uncertainties better understood. It is now well accepted and verified that many biological organisms (e.g., trees, corals, plankton, animals) alter their growth and/or population dynamics in response to changing climate, and that these climate-induced changes are well recorded in past growth in living and dead (fossil) specimens or assemblages of organisms. Networks of tree ring width and tree ring density chronologies are used to infer past temperature changes based on calibration with temporally overlapping instrumental data. While these methods are heavily used, there are concerns regarding the distributions of available measurements, how well these sample the globe, and such issues as the degree to which the methods have spatial and seasonal biases or apparent divergence in the relationship with recent climate change. {6.2}

It is *very likely* that average NH temperatures during the second half of the 20th century were warmer than any other 50-year period in the last 500 years and *likely* the warmest in at least the past 1300 years. The data supporting these conclusions are most extensive over summer extratropical land areas (particularly for the longer time period; see Figure TS.20). These conclusions are based upon proxy data such as the width and density of a tree ring, the isotopic composition of various elements in ice or the chemical composition of a growth band in corals, requiring analysis to derive temperature information and associated uncertainties. Among the key uncertainties are that temperature and precipitation are difficult to separate in some cases, or are representative of particular seasons rather than full years. There are now improved and expanded data since the TAR, including, for example, measurements at a larger number of sites, improved analysis of borehole temperature data and more extensive analyses of glaciers, corals and sediments. However, palaeoclimatic data are more limited than the instrumental record since 1850 in both space and time, so that statistical methods are employed to construct global averages, and these are subject to uncertainties as well. Current data are too limited to allow a similar evaluation of the SH temperatures prior to the period of instrumental data. {6.6, 6.7}

Some post-TAR studies indicate greater multi-centennial NH variability than was shown in the TAR, due to the particular proxies used and the specific statistical methods of processing and/or scaling them to represent past temperatures. The additional variability implies cooler conditions, predominantly during the 12th to 14th, the 17th and the 19th centuries; these are *likely* linked to natural forcings due to volcanic eruptions and/or solar activity. For example, reconstructions suggest decreased solar activity and increased volcanic activity in the 17th century as compared to current conditions. One reconstruction suggests slightly warmer conditions in the 11th century than those indicated in the TAR, but within the uncertainties quoted in the TAR. {6.6}

The ice core CO_2 record over the past millennium provides an additional constraint on natural climate variability. The amplitudes of the pre-industrial, decadal-scale NH temperature changes from the proxy-based reconstructions (<1°C) are broadly consistent with the ice core CO_2 record and understanding of the strength

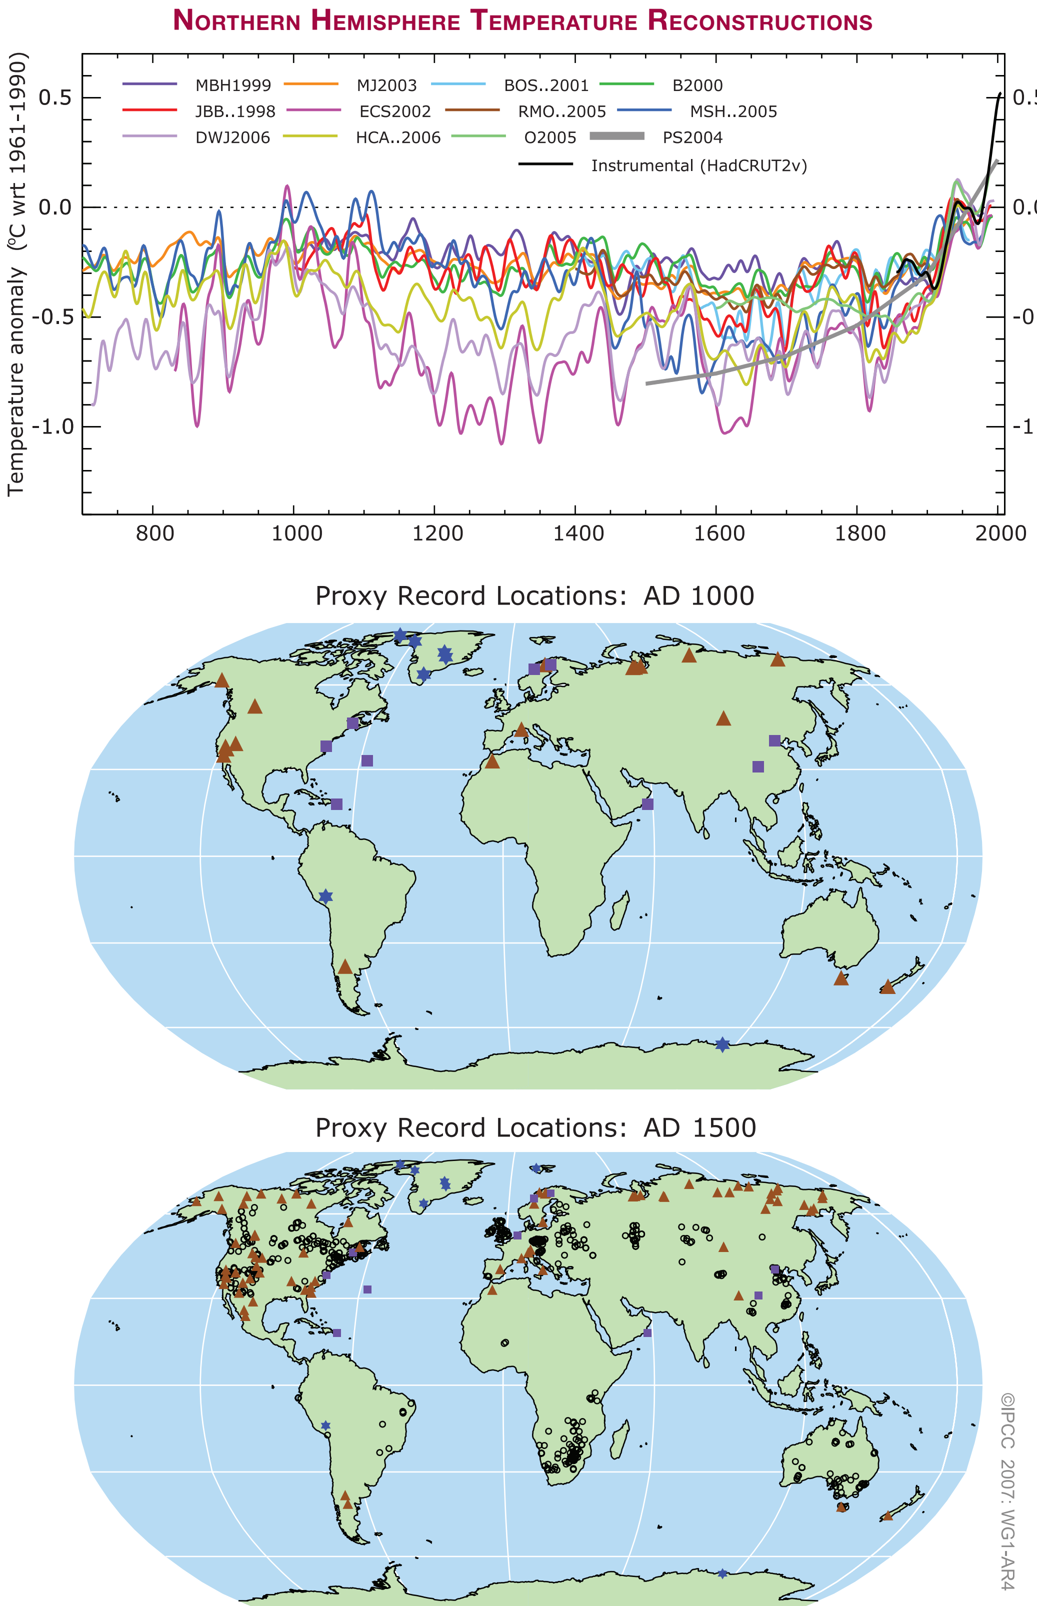


Figure TS.20. *(Top) Records of Northern Hemisphere temperature variation during the last 1300 years with 12 reconstructions using multiple climate proxy records shown in colour and instrumental records shown in black. (Middle and Bottom) Locations of temperature-sensitive proxy records with data back to AD 1000 and AD 1500 (tree rings: brown triangles; boreholes: black circles; ice core/ice boreholes: blue stars; other records including low-resolution records: purple squares). Data sources are given in Table 6.1, Figure 6.10 and are discussed in Chapter 6. {Figures 6.10 and 6.11}*

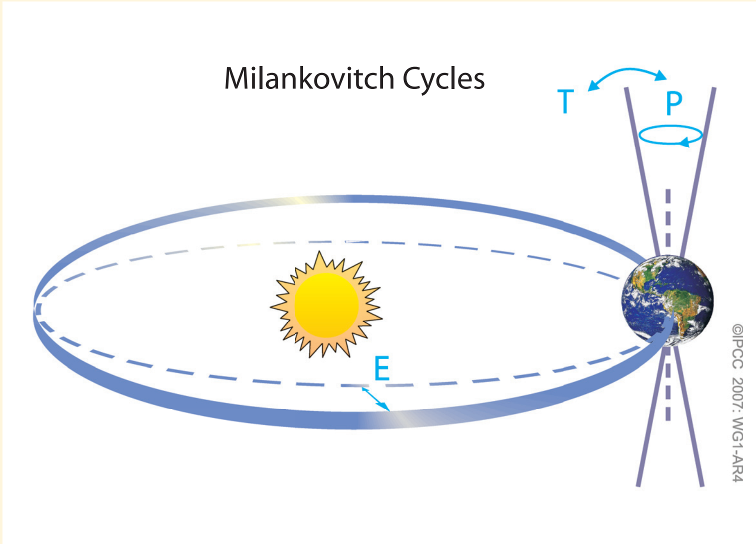
Box TS.6: Orbital Forcing

It is well known from astronomical calculations that periodic changes in characteristics of the Earth's orbit around the Sun control the seasonal and latitudinal distribution of incoming solar radiation at the top of the atmosphere (hereafter called 'insolation'). Past and future changes in insolation can be calculated over several millions of years with a high degree of confidence. {6.4}

Precession refers to changes in the time of the year when the Earth is closest to the Sun, with quasi-periodicities of about 19,000 and 23,000 years. As a result, changes in the position and duration of the seasons on the orbit strongly modulate the latitudinal and seasonal distribution of insolation. Seasonal changes in insolation are much larger than annual mean changes and can reach 60 W m^{-2} (Box TS.6, Figure 1).

The obliquity (tilt) of the Earth's axis varies between about 22° and 24.5° with two neighbouring quasi-periodicities of around 41,000 years. Changes in obliquity modulate seasonal contrasts as well as annual mean insolation changes with opposite effects at low vs. high latitudes (and therefore no effect on global average insolation) {6.4}.

The eccentricity of the Earth's orbit around the Sun has longer quasi-periodicities at 400,000 years and around 100,000 years. Changes in eccentricity alone have limited impacts on insolation, due to the resulting very small changes in the distance between the Sun and the Earth. However, changes in eccentricity interact with seasonal effects induced by obliquity and precession of the equinoxes. During periods of low eccentricity, such as about 400,000 years ago and during the next 100,000 years, seasonal insolation changes induced by precession are not as large as during periods of larger eccentricity (Box TS.6, Figure 1). {6.4}



Box TS.6, Figure 1. *Schematic of the Earth's orbital changes (Milankovitch cycles) that drive the ice age cycles. 'T' denotes changes in the tilt (or obliquity) of the Earth's axis, 'E' denotes changes in the eccentricity of the orbit and 'P' denotes precession, that is, changes in the direction of the axis tilt at a given point of the orbit. {FAQ 6.1, Figure 1}*

The Milankovitch, or 'orbital' theory of the ice ages is now well developed. Ice ages are generally triggered by minima in high-latitude NH summer insolation, enabling winter snowfall to persist through the year and therefore accumulate to build NH glacial ice sheets. Similarly, times with especially intense high-latitude NH summer insolation, determined by orbital changes, are thought to trigger rapid deglaciations, associated climate change and sea level rise. These orbital forcings determine the pacing of climatic changes, while the large responses appear to be determined by strong feedback processes that amplify the orbital forcing. Over multi-millennial time scales, orbital forcing also exerts a major influence on key climate systems such as the Earth's major monsoons, global ocean circulation and the greenhouse gas content of the atmosphere. {6.4}

Available evidence indicates that the current warming will not be mitigated by a natural cooling trend towards glacial conditions. Understanding of the Earth's response to orbital forcing indicates that the Earth would not naturally enter another ice age for at least 30,000 years. {6.4, FAQ 6.1} of the carbon cycle-climate feedback. Atmospheric CO_2 and temperature in Antarctica co-varied over the past 650,000 years. Available data suggest that CO_2 acts as an amplifying feedback. {6.4, 6.6}

Changes in glaciers are evident in Holocene data, but these changes were caused by different processes than the late 20th-century retreat. Glaciers of several mountain regions in the NH retreated in response to orbitally forced regional warmth between 11,000 and 5000 years ago, and were smaller than at the end of the 20th century (or even absent) at times prior to 5000 years ago. The current near-global retreat of mountain glaciers cannot be due to the same causes, because decreased summer insolation during the past few thousand years in the NH should be favourable to the growth of glaciers. {6.5}

Palaeoclimatic data provide evidence for changes in many regional climates. The strength and frequency of ENSO events have varied in past climates. There is evidence that the strength of the Asian monsoon, and hence precipitation amount, can change abruptly. The palaeoclimatic records of northern and eastern Africa and of North America indicate that droughts lasting decades to centuries are a recurrent feature of climate in these regions, so that recent droughts in North America and northern Africa are not unprecedented. Individual decadal-resolution palaeoclimatic data sets support the existence of regional quasi-periodic climate variability, but it is *unlikely* that these regional signals were coherent at the global scale. {6.5, 6.6}

Strong evidence from ocean sediment data and from modelling links abrupt climate changes during the last glacial period and glacial-interglacial transition to changes in the Atlantic Ocean circulation. Current understanding suggests that the ocean circulation can become unstable and change rapidly when critical thresholds are crossed. These events have affected temperature by up to 16°C in Greenland and have influenced tropical rainfall patterns. They were probably associated with a redistribution of heat between the NH and SH rather than with large changes in global mean temperature. Such events have not been observed during the past 8000 years. {6.4}

The Arctic and the Last Interglacial

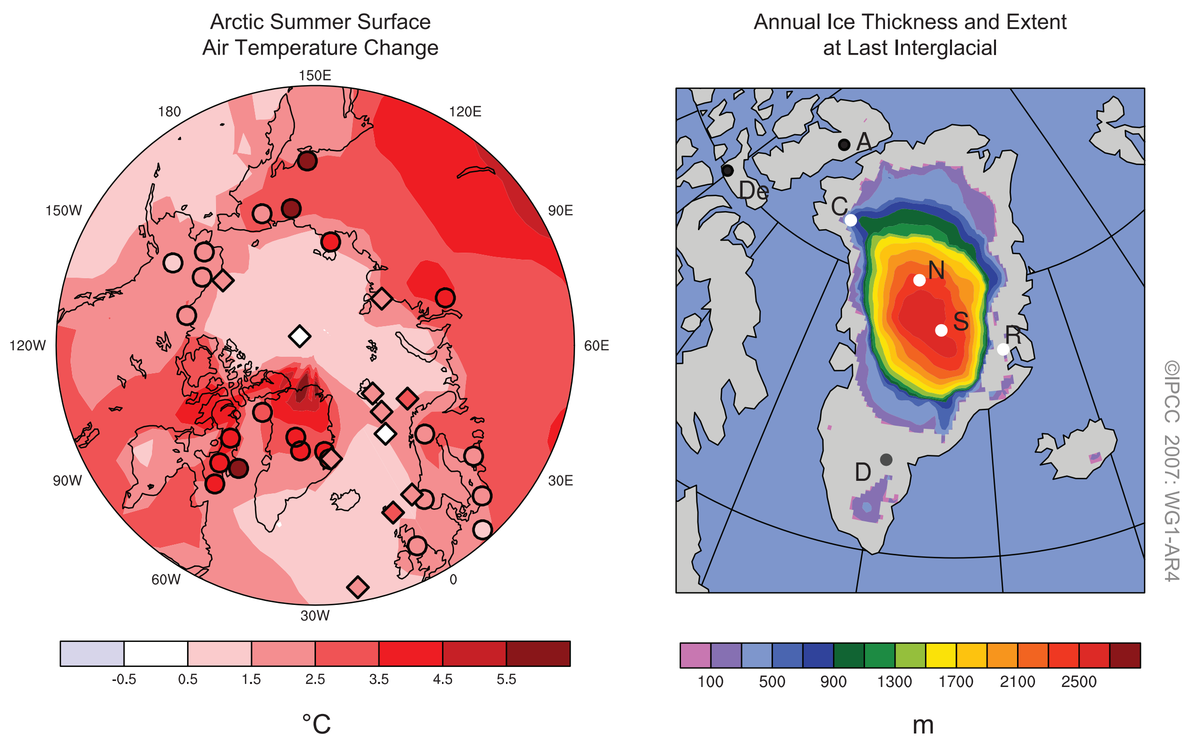


Figure TS.21. *Summer surface air temperature change relative to the present over the Arctic (left) and ice thickness and extent for Greenland and western arctic glaciers (right) for the last interglacial, approximately 125,000 years ago, from a multi-model and multi-proxy synthesis. (Left) A multi-model simulation of summer warming during the last interglacial is overlain by proxy estimates of maximum summer warming from terrestrial (circles) and marine (diamonds) sites. (Right) Extents and thicknesses of the Greenland Ice Sheet and western Canadian and Iceland glaciers at their minimum extent during the last interglacial, shown as a multi-model average from three ice models. Ice core observations indicate ice during the last interglacial at sites (white dots), Renland (R), North Greenland Ice Core Project (N), Summit (S, GRIP and GISP2) and possibly Camp Century (C), but no ice at sites (black dots): Devon (De) and Agassiz (A).Evidence for LIG ice at Dye-3 (D, grey dot) is equivocal. {Figure 6.6}*

Confidence in the understanding of past climate change and changes in orbital forcing is strengthened by the improved ability of current models to simulate past climate conditions. The Last Glacial Maximum (LGM; the last 'ice age' about 21,000 years ago) and the mid-Holocene (6000 years ago) were different from the current climate not because of random variability, but because of altered seasonal and global forcing linked to known differences in the Earth's orbit (see Box TS.6). Biogeochemical and biogeophysical feedbacks amplified the response to orbital forcings. Comparisons between simulated and reconstructed conditions in the LGM demonstrate that models capture the broad features of inferred changes in the temperature and precipitation patterns. For the mid-Holocene, coupled climate models are able to simulate mid-latitude warming and enhanced monsoons, with little change in global mean temperature (<0.4°C), consistent with our understanding of orbital forcing. {6.2, 6.4, 6.5, 9.3}

Global average sea level was likely between 4 and 6 m higher during the last interglacial period, about 125,000 years ago, than during the 20th century, mainly due to the retreat of polar ice (Figure TS.21). Ice core data suggest that the Greenland Summit region was ice-covered during this period, but reductions in the ice sheet extent are indicated in parts of southern Greenland. Ice core data also indicate that average polar temperatures at that time were 3°C to 5°C warmer than the 20th century because of differences in the Earth's orbit. The Greenland Ice Sheet and other arctic ice fields likely contributed no more than 4 m of the observed sea level rise, implying that there may also have been a contribution from Antarctica. {6.4}

TS.4 Understanding and Attributing Climate Change

Attribution evaluates whether observed changes are consistent with quantitative responses to different forcings obtained in well-tested models, and are not consistent with alternative physically plausible explanations. The first IPCC Assessment Report (FAR) contained little observational evidence of a detectable anthropogenic influence on climate. Six years later, the IPCC Second Assessment Report (SAR) concluded that the balance of evidence suggested a discernible human influence on the climate of the 20th century. The TAR concluded that 'most of the observed warming over the last 50 years is likely to have been due to the increase in greenhouse gas concentrations'. Confidence in the assessment of the human contributions to recent climate change has increased considerably since the TAR, in part because of stronger signals obtained from longer records, and an expanded and improved range of observations allowing attribution of warming to be more fully addressed jointly with other changes in the climate system. Some apparent inconsistencies in the observational record (e.g., in the vertical profile of temperature changes) have been largely resolved. There have been improvements in the simulation of many aspects of present mean climate and its variability on seasonal to inter-decadal time scales, although uncertainties remain (see Box TS.7). Models now employ more detailed representations of processes related to aerosol and other forcings. Simulations of 20th-century climate change have used many more models and much more complete anthropogenic and natural forcings than were available for the TAR. Available multi-model ensembles increase confidence in attribution results by providing an improved representation of model uncertainty. An anthropogenic signal has now more clearly emerged in formal attribution studies of aspects of the climate system beyond global-scale atmospheric temperature, including changes in global ocean heat content, continental-scale temperature trends, temperature extremes, circulation and arctic sea ice extent. {9.1}

TS.4.1 Advances in Attribution of Changes in Global-Scale Temperature in the Instrumental Period: Atmosphere, Ocean and Ice

Anthropogenic warming of the climate system is widespread and can be detected in temperature observations taken at the surface, in the free atmosphere and in the oceans. {3.2, 3.4, 9.4}

Evidence of the effect of external influences, both anthropogenic and natural, on the climate system has continued to accumulate since the TAR. Model and data improvements, ensemble simulations and improved representations of aerosol and greenhouse gas forcing along with other influences lead to greater confidence that most current models reproduce large-scale forced variability of the atmosphere on decadal and inter-decadal time scales quite well. These advances confirm that past climate variations at large spatial scales have been strongly influenced by external forcings. However, uncertainties still exist in the magnitude and temporal evolution of estimated contributions from individual forcings other than well-mixed greenhouse gases, due, for

Box TS.7: Evaluation of Atmosphere-Ocean General Circulation Models

Atmosphere-ocean general circulation models (AOGCMs) are the primary tool used for understanding and attribution of past climate variations, and for future projections. Since there are no historical perturbations to radiative forcing that are fully analogous to the human-induced perturbations expected over the 21st century, confidence in the models must be built from a number of indirect methods, described below. In each of these areas there have been substantial advances since the TAR, increasing overall confidence in models. {8.1}

Enhanced scrutiny and analysis of model behaviour has been facilitated by internationally coordinated efforts to collect and disseminate output from model experiments performed under common conditions. This has encouraged a more comprehensive and open evaluation of models, encompassing a diversity of perspectives. {8.1}

Projections for different scales and different periods using global climate models. Climate models project the climate for several decades or longer into the future. Since the details of individual weather systems are not being tracked and forecast, the initial atmospheric conditions are much less important than for weather forecast models. For climate projections, the forcings are of much greater importance. These forcings include the amount of solar energy reaching the Earth, the amount of particulate matter from volcanic eruptions in the atmosphere, and the concentrations of anthropogenic gases and particles in the atmosphere. As the area of interest moves from global to regional to local, or the time scale of interest shortens, the amplitude of variability linked to weather increases relative to the signal of long-term climate change. This makes detection of the climate change signal more difficult at smaller scales. Conditions in the oceans are important as well, especially for interannual and decadal time scales. {FAQ 1.2, 9.4, 11.1}

Model formulation. The formulation of AOGCMs has developed through improved spatial resolution and improvements to numerical schemes and parametrizations (e.g., sea ice, atmospheric boundary layer, ocean mixing). More processes have been included in many models, including a number of key processes important for forcing (e.g., aerosols are now modelled interactively in many models). Most models now maintain a stable climate without use of flux adjustments, although some long-term trends remain in AOGCM control integrations, for example, due to slow processes in the ocean. {8.2, 8.3}

Simulation of present climate. As a result of improvements in model formulation, there have been improvements in the simulation of many aspects of present mean climate. Simulations of precipitation, sea level pressure and surface temperature have each improved overall, but deficiencies remain, notably in tropical precipitation. While significant deficiencies remain in the simulation of clouds (and corresponding feedbacks affecting climate sensitivity), some models have demonstrated improvements in the simulation of certain cloud regimes (notably marine stratocumulus). Simulation of extreme events (especially extreme temperature) has improved, but models generally simulate too little precipitation in the most extreme events. Simulation of extratropical cyclones has improved. Some models used for projections of tropical cyclone changes can simulate successfully the observed frequency and distribution of tropical cyclones. Improved simulations have been achieved for ocean water mass structure, the meridional overturning circulation and ocean heat transport. However most models show some biases in their simulation of the Southern Ocean, leading to some uncertainty in modelled ocean heat uptake when climate changes. {8.3, 8.5, 8.6}

Simulation of modes of climate variability. Models simulate dominant modes of extratropical climate variability that resemble the observed ones (NAM/SAM, PNA, PDO) but they still have problems in representing aspects of them. Some models can now simulate important aspects of ENSO, while simulation of the Madden-Julian Oscillation remains generally unsatisfactory. {8.4}

Simulation of past climate variations. Advances have been made in the simulation of past climate variations. Independently of any attribution of those changes, the ability of climate models to provide a physically self-consistent explanation of observed climate variations on various time scales builds confidence that the models are capturing many key processes for the evolution of 21st-century climate. Recent advances include success in modelling observed changes in a wider range of climate variables over the 20th century (e.g., continental-scale surface temperatures and extremes, sea ice extent, ocean heat content trends and land precipitation). There has also been progress in the ability to model many of the general features of past, very different climate states such as the mid-Holocene and the LGM using identical or related models to those used for studying current climate. Information on factors treated as boundary conditions in palaeoclimate calculations include the different states of ice sheets in those periods. The broad predictions of earlier climate models, of increasing global temperatures in response to increasing greenhouse gases, have been borne out by subsequent observations. This strengthens confidence in near-term climate projections and understanding of related climate change commitments. {6.4, 6.5, 8.1, 9.3–9.5}

(continued)

Weather and seasonal prediction using climate models. A few climate models have been tested for (and shown) capability in initial value prediction, on time scales from weather forecasting (a few days) to seasonal climate variations, when initialised with appropriate observations. While the predictive capability of models in this mode of operation does not necessarily imply that they will show the correct response to changes in climate forcing agents such as greenhouse gases, it does increase confidence that they are adequately representing some key processes and teleconnections in the climate system. {8.4}

Measures of model projection accuracy. The possibility of developing model capability measures ('metrics'), based on the above evaluation methods, that can be used to narrow uncertainty by providing quantitative constraints on model climate projections, has been explored for the first time using model ensembles. While these methods show promise, a proven set of measures has yet to be established. {8.1, 9.6, 10.5}

example, to uncertainties in model responses to forcing. Some potentially important forcings such as black carbon aerosols have not yet been considered in most formal detection and attribution studies. Uncertainties remain in estimates of natural internal climate variability. For example, there are discrepancies between estimates of ocean heat content variability from models and observations, although poor sampling of parts of the world ocean may explain this discrepancy. In addition, internal variability is difficult to estimate from available observational records since these are influenced by external forcing, and because records are not long enough in the case of instrumental data, or precise enough in the case of proxy reconstructions, to provide complete descriptions of variability on decadal and longer time scales (see Figure TS.22 and Box TS.7). {8.2–8.4, 8.6, 9.2–9.4}

It is *extremely unlikely* (<5%) that the global pattern of warming observed during the past half century can be explained without external forcing. These changes took place over a time period when non-anthropogenic forcing factors (i.e., the sum of solar and volcanic forcing) would be *likely* to have produced cooling, not warming (see Figure TS.23). Attribution studies show that it is *very likely* that these natural forcing factors alone cannot account for the observed warming (see Figure TS.23). There is also increased confidence that natural internal variability cannot account for the observed changes, due in part to improved studies demonstrating that the warming occurred in both oceans and atmosphere, together with observed ice mass losses. {2.9, 3.2, 5.2, 9.4, 9.5, 9.7}

It is *very likely* that anthropogenic greenhouse gas increases caused most of the observed increase in global average temperatures since the mid-20th century. Without the cooling effect of atmospheric aerosols, it is *likely* that greenhouse gases alone would have caused a greater global mean temperature rise than that observed during the last 50 years. A key factor in identifying the aerosol fingerprint, and therefore the amount of cooling counteracting greenhouse warming, is the temperature change through time (see Figure TS.23), as well as the hemispheric warming contrast. The conclusion that greenhouse gas forcing has been dominant takes into account observational and forcing uncertainties, and is robust to the use of different climate models, different methods for estimating the responses to external forcing and different analysis techniques. It also allows for possible amplification of the response to solar forcing. {2.9, 6.6, 9.1, 9.2, 9.4}

Widespread warming has been detected in ocean temperatures. Formal attribution studies now suggest that it is *likely* that anthropogenic forcing has contributed to the observed warming of the upper several hundred metres of the global ocean during the latter half of the 20th century. {5.2, 9.5}

Anthropogenic forcing has *likely* contributed to recent decreases in arctic sea ice extent. Changes in arctic sea ice are expected given the observed enhanced arctic warming. Attribution studies and improvements in the modelled representation of sea ice and ocean heat transport strengthen the confidence in this conclusion. {3.3, 4.4, 8.2, 8.3, 9.5}

It is *very likely* that the response to anthropogenic forcing contributed to sea level rise during the latter half of the 20th century, but decadal variability in sea level rise remains poorly understood. Modelled estimates of the contribution to sea level rise from thermal expansion are in good agreement with estimates based on observations during 1961 to 2003, although the budget for sea level rise over that interval is not closed. The observed increase in the rate of loss of mass from glaciers and ice caps is proportional to the global average temperature rise, as expected qualitatively from physical considerations (see Table TS.3). The greater rate of sea level rise in 1993 to 2003 than in 1961 to 2003 may be linked to increasing anthropogenic forcing, which has

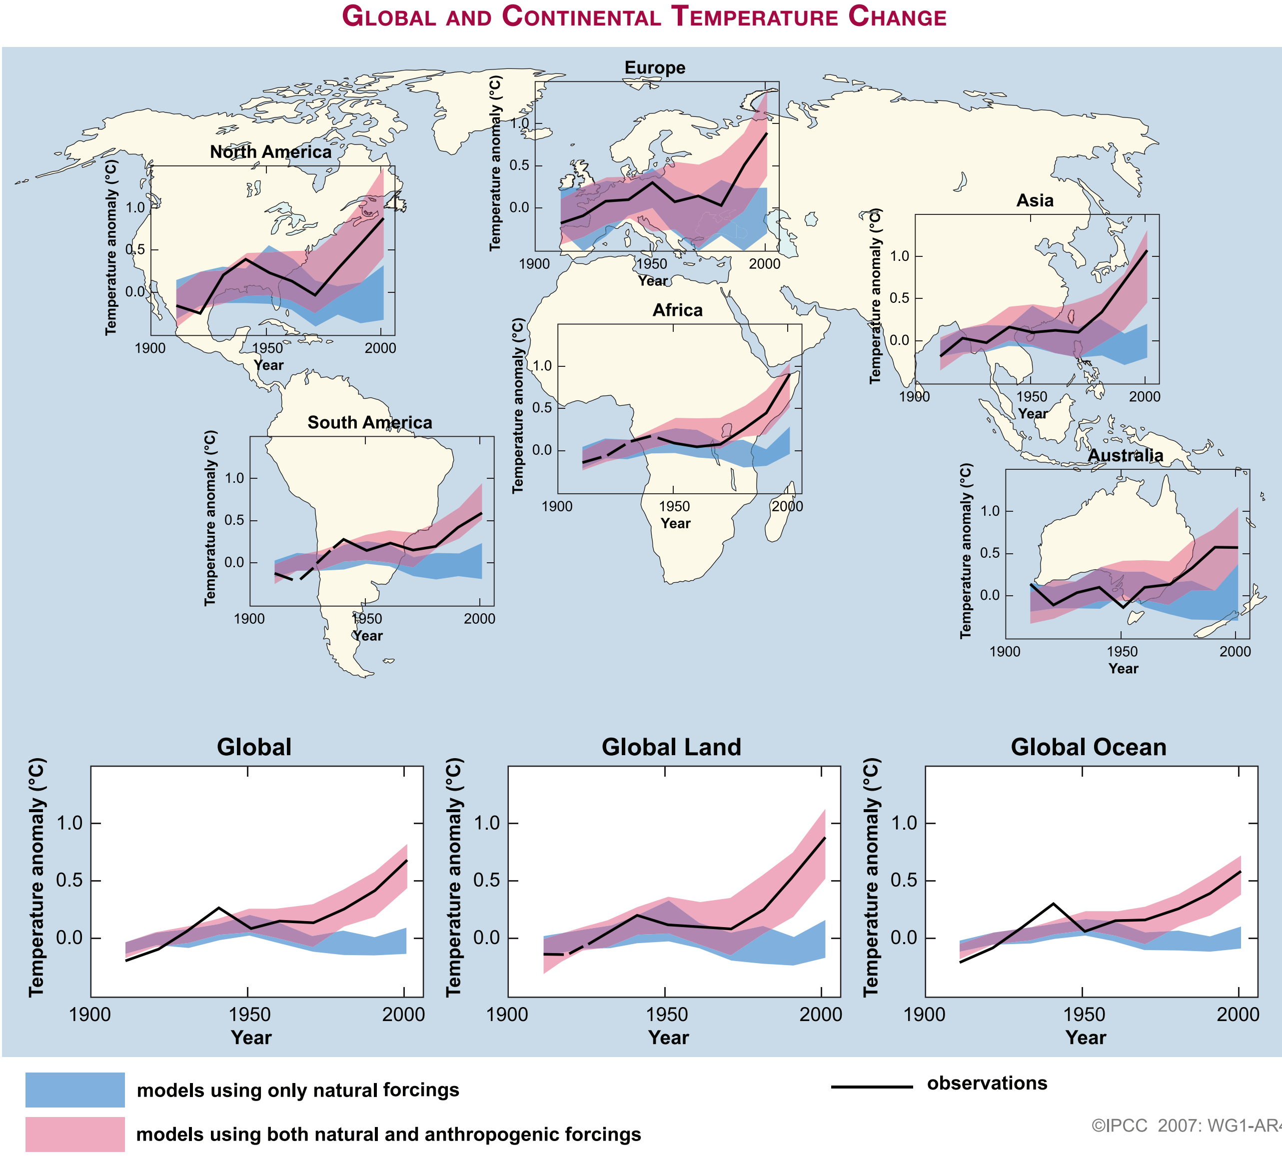

Figure TS.22. *Comparison of observed continental- and global-scale changes in surface temperature with results simulated by climate models using natural and anthropogenic forcings. Decadal averages of observations are shown for the period 1906 to 2005 (black line) plotted against the centre of the decade and relative to the corresponding average for 1901 to 1950. Lines are dashed where spatial coverage is less than 50%. Blue shaded bands show the 5% to 95% range for 19 simulations from 5 climate models using only the natural forcings due to solar activity and volcanoes. Red shaded bands show the 5% to 95% range for 58 simulations from 14 climate models using both natural and anthropogenic forcings. Data sources and models used are described in Section 9.4, FAQ 9.2, Table 8.1 and the supplementary information for Chapter 9. {FAQ 9.2, Figure 1}*

likely contributed to the observed warming of the upper ocean and widespread glacier retreat. On the other hand, the tide gauge record of global mean sea level suggests that similarly large rates may have occurred in previous 10-year periods since 1950, implying that natural internal variability could also be a factor in the high rates for 1993 to 2003 period. Observed decadal variability in the tide gauge record is larger than can be explained by variability in observationally based estimates of thermal expansion and land ice changes. Further, the observed decadal variability in thermal expansion is larger than simulated by models for the 20th century. Thus, the physical causes of the variability seen in the tide gauge record are uncertain. These unresolved issues relating to sea level change and its decadal variability during 1961 to 2003 make it unclear how much of the higher rate of sea level rise in 1993 to 2003 is due to natural internal variability and how much to anthropogenic climate change. {5.5, 9.5}

TS.4.2 Attribution of Spatial and Temporal Changes in Temperature

The observed pattern of tropospheric warming and stratospheric cooling is *very likely* due to the influence of anthropogenic forcing, particularly that due to greenhouse gas increases and stratospheric ozone depletion. New analyses since the TAR show that this pattern corresponds to an increase in the height of the tropopause that is *likely* due largely to greenhouse gas and stratospheric ozone changes. Significant uncertainty remains in the estimation of tropospheric temperature trends, particularly from the radiosonde record. {3.2, 3.4, 9.4}

It is *likely* that there has been a substantial anthropogenic contribution to surface temperature increases averaged over every continent except Antarctica since the middle of the 20th century. Antarctica has insufficient observational coverage to make an assessment. Anthropogenic warming has also been identified in some sub-continental land areas. The ability of coupled climate models to simulate the temperature evolution on each of six continents provides stronger evidence of human influence on the global climate than was available in the TAR. No coupled global climate model that has used natural forcing only has reproduced the observed global mean warming trend, or the continental mean warming trends in individual

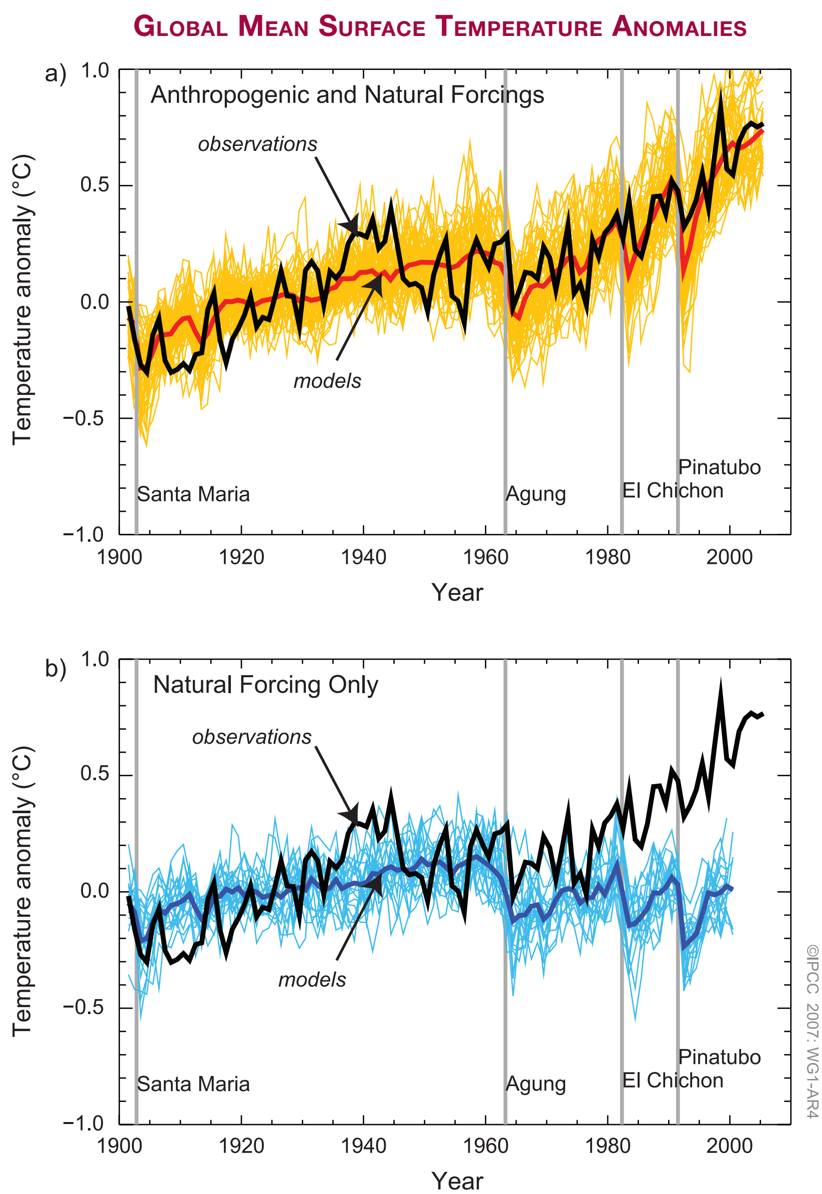

Figure TS.23. *(a) Global mean surface temperature anomalies relative to the period 1901 to 1950, as observed (black line) and as obtained from simulations with both anthropogenic and natural forcings. The thick red curve shows the multi-model ensemble mean and the thin yellow curves show the individual simulations. Vertical grey lines indicate the timing of major volcanic events. (b) As in (a), except that the simulated global mean temperature anomalies are for natural forcings only. The thick blue curve shows the multi-model ensemble mean and the thin lighter blue curves show individual simulations. Each simulation was sampled so that coverage corresponds to that of the observations. {Figure 9.5}* continents (except Antarctica) over the second half of the 20th century. {9.4}

Difficulties remain in attributing temperature changes at smaller than continental scales and over time scales of less than 50 years. Attribution results at these scales have, with limited exceptions, not been established. Averaging over smaller regions reduces the natural variability less than does averaging over large regions, making it more difficult to distinguish between changes expected from external forcing and variability. In addition, temperature changes associated with some modes of variability are poorly simulated by models in some regions and seasons. Furthermore, the small-scale details of external forcing and the response simulated by models are less credible than large-scale features. {8.3, 9.4}

Surface temperature extremes have *likely* been affected by anthropogenic forcing. Many indicators of extremes, including the annual numbers and most extreme values of warm and cold days and nights, as well as numbers of frost days, show changes that are consistent with warming. Anthropogenic influence has been detected in some of these indices, and there is evidence that anthropogenic forcing may have substantially increased the risk of extremely warm summer conditions regionally, such as the 2003 European heat wave. {9.4}

December - February Sea Level Pressure Trends

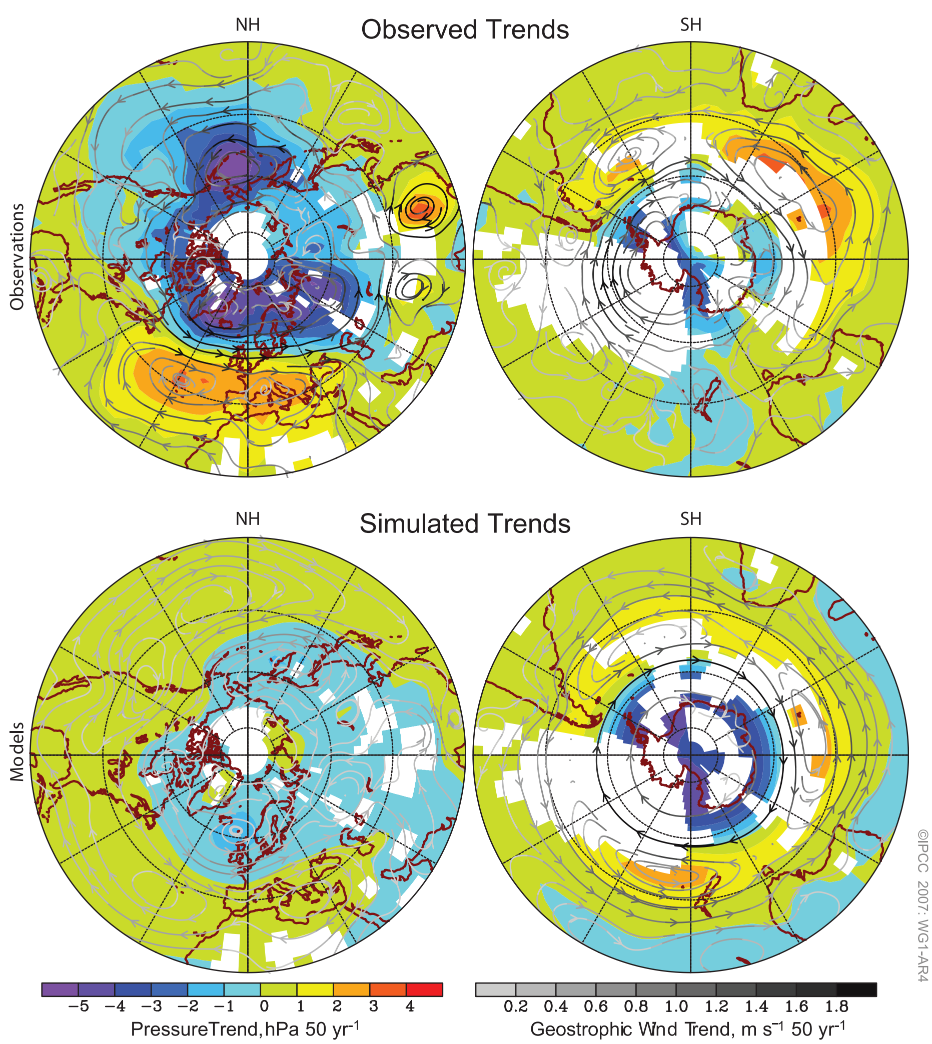

Figure TS.24. *December through February sea level pressure trends based on decadal means for the period 1955 to 2005. (Top) Trends estimated from an observational data set and displayed in regions where there is observational coverage. (Bottom) Mean trends simulated in response to natural and anthropogenic forcing changes in eight coupled models. The model-simulated trends are displayed only where observationally based trends are displayed. Streamlines, which are not masked, indicate the direction of the trends in the geostrophic wind derived from the trends in sea level pressure, and the shading of the streamlines indicates the magnitude of the change, with darker streamlines corresponding to larger changes in geostrophic wind. Data sources and models are described in Chapter 9 and its supplementary material, and Table 8.1 provides model details. {Figure 9.16}*

TS.4.3 Attribution of Changes in Circulation, Precipitation and Other Climate Variables

Trends in the Northern and Southern Annular Modes over recent decades, which correspond to sea level pressure reductions over the poles and related changes in atmospheric circulation, are *likely* related in part to human activity (see Figure TS.24). Models reproduce the sign of the NAM trend, but the simulated response is smaller than observed. Models including both greenhouse gas and stratospheric ozone changes simulate a realistic trend in the SAM, leading to a detectable human influence on global sea level pressure that is also consistent with the observed cooling trend in surface climate over parts of Antarctica. These changes in hemispheric circulation and their attribution to human activity imply that anthropogenic effects have *likely* contributed to changes in mid- and high-latitude patterns of circulation and temperature, as well as changes in winds and storm tracks. However, quantitative effects are uncertain because simulated responses to 20th century forcing change for the NH agree only qualitatively and not quantitatively with observations of these variables. {3.6, 9.5, 10.3}

There is some evidence of the impact of external influences on the hydrological cycle. The observed large-scale pattern of changes in land precipitation over the 20th century is qualitatively consistent with simulations, suggestive of a human influence. An observed global trend towards increases in drought in the second half of the 20th century has been reproduced with a model by taking anthropogenic and natural forcing into account. A number of studies have now demonstrated that changes in land use, due for example to overgrazing and conversion of woodland to agriculture, are *unlikely* to have been the primary cause of Sahelian and Australian droughts. Comparisons between observations and models suggest that changes in monsoons, storm intensities and Sahelian rainfall are related at least in part to changes in observed SSTs. Changes in global SSTs are expected to be affected by anthropogenic forcing, but an association of regional SST changes with forcing has not been established. Changes in rainfall depend not just upon SSTs but also upon changes in the spatial and temporal SST patterns and regional changes in atmospheric circulation, making attribution to human influences difficult. {3.3, 9.5, 10.3, 11.2}

TS.4.4 Palaeoclimate Studies of Attribution

It is *very likely* that climate changes of at least the seven centuries prior to 1950 were not due to unforced variability alone. Detection and attribution studies indicate that a substantial fraction of pre-industrial NH inter-decadal temperature variability contained in reconstructions for those centuries is *very likely* attributable to natural external forcing. Such forcing includes episodic cooling due to known volcanic eruptions, a number of which were larger than those of the 20th century (based on evidence such as ice cores), and long-term variations in solar irradiance, such as reduced radiation during the Maunder Minimum. Further, it is *likely* that anthropogenic forcing contributed to the early 20th-century warming evident in these records. Uncertainties are unlikely to lead to a spurious agreement between temperature reconstructions and forcing reconstructions as they are derived from independent proxies. Insufficient data are available to make a similar SH evaluation. {6.6, 9.3}

TS.4.5 Climate Response to Radiative Forcing

Specification of a *likely* range and a most *likely* value for equilibrium climate sensitivity[8] in this report represents significant progress in quantifying the climate system response to radiative forcing since the TAR and an advance in challenges to understanding that have persisted for over 30 years. A range for equilibrium climate sensitivity – the equilibrium global average warming expected if CO_2 concentrations were to be sustained at double their pre-industrial values (about 550 ppm) – was given in the TAR as between 1.5°C and 4.5°C. It has not been possible previously to provide a best estimate or to estimate the probability that climate sensitivity might fall outside that quoted range. Several approaches are used in this assessment to constrain climate sensitivity, including the use of AOGCMs, examination of the transient evolution of temperature (surface, upper air and ocean) over the last 150 years and examination of the rapid response of the global climate system to changes in the forcing caused by volcanic eruptions (see Figure TS.25). These are complemented by estimates based upon palaeoclimate studies such as reconstructions of the NH temperature record of the past millennium and the LGM. Large ensembles of climate model simulations have shown that the ability of models to simulate present climate has value in constraining climate sensitivity. {8.1, 8.6, 9.6, Box 10.2}

8 See the Glossary for a detailed definition of climate sensitivity.

Analysis of models together with constraints from observations suggest that the equilibrium climate sensitivity is *likely* to be in the range 2°C to 4.5°C, with a best estimate value of about 3°C. It is *very unlikely* to be less than 1.5°C. Values substantially higher than 4.5°C cannot be excluded, but agreement with observations is not as good for those values. Probability density functions derived from different information and approaches generally tend to have a long tail towards high values exceeding 4.5°C. Analysis of climate and forcing evolution over previous centuries and model ensemble studies do not rule out climate sensitivity being as high as 6°C or more. One factor in this is the possibility of small net radiative forcing over the 20th century if aerosol indirect cooling effects were at the upper end of their uncertainty range, thus cancelling most of the positive forcing due to greenhouse gases. However, there is no well-established way of estimating a single probability distribution function from individual results taking account of the different assumptions in each study. The lack of strong constraints limiting high climate sensitivities prevents the specification of a 95th percentile bound or a very likely range for climate sensitivity. {Box 10.2}

There is now increased confidence in the understanding of key climate processes that are important to climate sensitivity due to improved analyses and comparisons of models to one another and to observations. Water vapour changes dominate the feedbacks affecting climate sensitivity and are now better understood. New observational and modelling evidence strongly favours a combined water vapour-lapse rate[9] feedback of around the strength found in General Circulation Models (GCMs), that is, approximately 1 W m^{-2} per degree global temperature increase, corresponding to about a 50% amplification of global mean warming. Such GCMs have demonstrated an ability to simulate seasonal to inter-decadal humidity variations in the upper troposphere over land and ocean, and have successfully simulated the observed surface temperature and humidity changes associated with volcanic eruptions. Cloud feedbacks (particularly from low clouds) remain the largest source of uncertainty. Cryospheric feedbacks such as changes in snow cover have been shown to contribute less to the spread in model estimates of climate sensitivity than cloud or water vapour feedbacks, but they

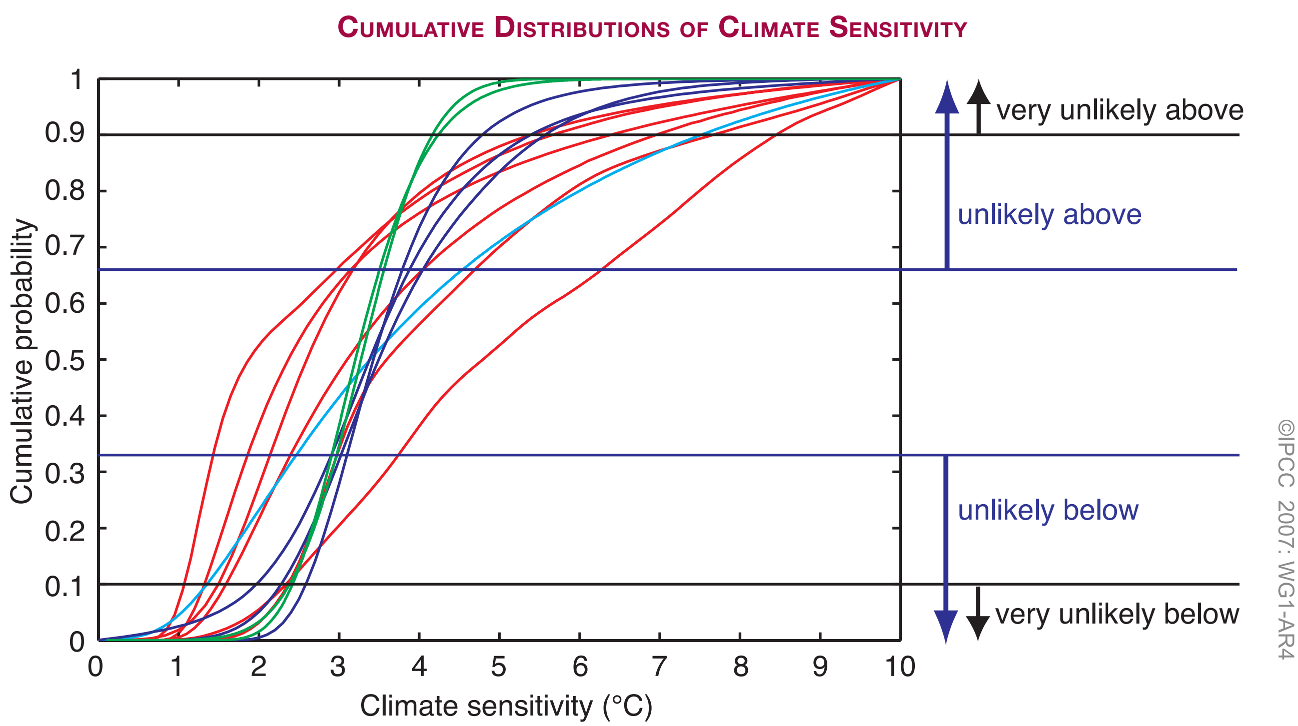

Figure TS.25. *Cumulative distributions of climate sensitivity derived from observed 20th-century warming (red), model climatology (blue), proxy evidence (cyan) and from climate sensitivities of AOGCMs (green). Horizontal lines and arrows mark the boundaries of the likelihood estimates defined in the IPCC Fourth Assessment Uncertainty Guidance Note (see Box TS.1). {Box 10.2, Figures 1 and 2}*

[9] The rate at which air temperature decreases with altitude.

can be important for regional climate responses at mid- and high latitudes. A new model intercomparison suggests that differences in radiative transfer formulations also contribute to the range. {3.4, 8.6, 9.3, 9.4, 9.6, 10.2, Box 10.2}

Improved quantification of climate sensitivity allows estimation of best estimate equilibrium temperatures and ranges that could be expected if concentrations of CO_2 were to be stabilised at various levels based on global energy balance considerations (see Table TS.5). As in the estimate of climate sensitivity, a very likely upper bound cannot be established. Limitations to the concept of radiative forcing and climate sensitivity should be noted. Only a few AOGCMs have been run to equilibrium under elevated CO_2 concentrations, and some results show that climate feedbacks may change over long time scales, resulting in substantial deviations from estimates of warming based on equilibrium climate sensitivity inferred from mixed layer ocean models and past climate change. {10.7}

Agreement among models for projected transient climate change has also improved since the TAR. The range of transient climate responses (defined as the global average surface air temperature averaged over a 20-year period centred at the time of CO_2 doubling in a 1% yr^{-1} increase experiment) among models is smaller than the range in the equilibrium climate sensitivity. This parameter is now better constrained by multi-model ensembles and comparisons with observations; it is *very likely* to be greater than 1°C and *very unlikely* to be greater than 3°C. The transient climate response is related to sensitivity in a nonlinear way such that high sensitivities are not immediately manifested in the short-term response. Transient climate response is strongly affected by the rate of ocean heat uptake. Although the ocean models have improved, systematic model biases and limited ocean temperature data to evaluate transient ocean heat uptake affect the accuracy of current estimates. {8.3, 8.6, 9.4, 9.6, 10.5}

Table TS.5. *Best estimate, likely ranges and very likely lower bounds of global mean equilibrium surface temperature increase (°C) over pre-industrial temperatures for different levels of CO_2-equivalent radiative forcing, as derived from the climate sensitivity.*

Equilibrium CO_2–eq (ppm)	Temperature Increase (°C)		
	Best Estimate	*Very Likely* Above	*Likely* in the Range
350	1.0	0.5	0.6–1.4
450	2.1	1.0	1.4–3.1
550	2.9	1.5	1.9–4.4
650	3.6	1.8	2.4–5.5
750	4.3	2.1	2.8–6.4
1000	5.5	2.8	3.7–8.3
1200	6.3	3.1	4.2–9.4

TS.5 Projections of Future Changes in Climate

Since the TAR, there have been many important advances in the science of climate change projections. An unprecedented effort has been initiated to make new model results available for prompt scrutiny by researchers outside of the modelling centres. A set of coordinated, standard experiments was performed by 14 AOGCM modelling groups from 10 countries using 23 models. The resulting multi-model database of outputs, analysed by hundreds of researchers worldwide, forms the basis for much of this assessment of model results. Many advances have come from the use of multi-member ensembles from single models (e.g., to test the sensitivity of response to initial conditions) and from multi-model ensembles. These two different types of ensembles allow more robust studies of the range of model results and more quantitative model evaluation against observations, and provide new information on simulated statistical variability. {8.1, 8.3, 9.4, 9.5, 10.1}

A number of methods for providing probabilistic climate change projections, both for global means and geographical depictions, have emerged since the TAR and are a focus of this report. These include methods based on results of AOGCM ensembles without formal application of observational constraints as well as methods based on detection algorithms and on large model ensembles that provide projections consistent with observations of climate change and their uncertainties. Some methods now explicitly account for key uncertainty sources such as climate feedbacks, ocean heat uptake, radiative forcing and the carbon cycle. Short-term projections are similarly constrained by observations of recent trends. Some studies have probed additional probabilistic issues, such as the likelihood of future changes in extremes such as heat waves that could occur due to human influences. Advances have also occurred since the TAR through broader ranges of studies of committed climate change and of carbon-climate feedbacks. {8.6, 9.6, 10.1, 10.3, 10.5}

These advances in the science of climate change modelling provide a probabilistic basis for distinguishing projections of climate change for different SRES marker scenarios. This is in contrast to the TAR where ranges for different marker scenarios could not be given in probabilistic terms. As a result, this assessment identifies and quantifies the difference in character between uncertainties that arise in climate modelling and those that arise from a lack of prior knowledge of decisions that will affect greenhouse gas emissions. A loss of policy-relevant information would result from combining probabilistic projections. For these reasons, projections for different emission scenarios are not combined in this report.

Model simulations used here consider the response of the physical climate system to a range of possible future conditions through use of idealised emissions or concentration assumptions. These include experiments with greenhouse gases and aerosols held constant at year 2000 levels, CO_2 doubling and quadrupling experiments, SRES marker scenarios for the 2000 to 2100 period, and experiments with greenhouse gases and aerosols held constant after 2100, providing new information on the physical aspects of long-term climate change and stabilisation. The SRES scenarios did not include climate initiatives. This Working Group I assessment does not evaluate the plausibility or likelihood of any specific emission scenario. {10.1, 10.3}

A new multi-model data set using Earth System Models of Intermediate Complexity (EMICs) complements AOGCM experiments to extend the time horizon for several more centuries in the future. This provides a more comprehensive range of model responses in this assessment as well as new information on climate change over long time scales when greenhouse gas and aerosol concentrations are held constant. Some AOGCMs and EMICs contain prognostic carbon cycle components, which permit estimation of the likely effects and associated uncertainties of carbon cycle feedbacks. {10.1}

Box TS.8: Hierarchy of Global Climate Models

Estimates of change in global mean temperature and sea level rise due to thermal expansion can be made using Simple Climate Models (SCMs) that represent the ocean-atmosphere system as a set of global or hemispheric boxes, and predict global surface temperature using an energy balance equation, a prescribed value of climate sensitivity and a basic representation of ocean heat uptake. Such models can also be coupled to simplified models of biogeochemical cycles and allow rapid estimation of the climate response to a wide range of emission scenarios. {8.8, 10.5}

Earth System Models of Intermediate Complexity (EMICs) include some dynamics of the atmospheric and oceanic circulations, or parametrizations thereof, and often include representations of biogeochemical cycles, but they commonly have reduced spatial resolution. These models can be used to investigate continental-scale climate change and long-term, large-scale effects of coupling between Earth system components using large ensembles of model runs or runs over many centuries. For both SCMs and EMICs it is computationally feasible to sample parameter spaces thoroughly, taking account of parameter uncertainties derived from tuning to more comprehensive climate models, matching observations and use of expert judgment. Thus, both types of model are well suited to the generation of probabilistic projections of future climate and allow a comparison of the 'response uncertainty' arising from uncertainty in climate model parameters with the 'scenario range' arising from the range of emission scenarios being considered. Earth System Models of Intermediate Complexity have been evaluated in greater depth than previously and intercomparison exercises have demonstrated that they are useful for studying questions involving long time scales or requiring large ensembles of simulations. {8.8, 10.5, 10.7}

The most comprehensive climate models are the AOGCMs. They include dynamical components describing atmospheric, oceanic and land surface processes, as well as sea ice and other components. Much progress has been made since the TAR (see Box TS.7), and there are over 20 models from different centres available for climate simulations. Although the large-scale dynamics of these models are comprehensive, parametrizations are still used to represent unresolved physical processes such as the formation of clouds and precipitation, ocean mixing due to wave processes and the formation of water masses, etc. Uncertainty in parametrizations is the primary reason why climate projections differ between different AOGCMs. While the resolution of AOGCMs is rapidly improving, it is often insufficient to capture the fine-scale structure of climatic variables in many regions. In such cases, the output from AOGCMs can be used to drive limited-area (or regional climate) models that combine the comprehensiveness of process representations comparable to AOGCMs with much higher spatial resolution. {8.2}

TS.5.1 Understanding Near-Term Climate Change

Knowledge of the climate system together with model simulations confirm that past changes in greenhouse gas concentrations will lead to a committed warming (see Box TS.9 for a definition) and future climate change. New model results for experiments in which concentrations of all forcing agents were held constant provide better estimates of the committed changes in atmospheric variables that would follow because of the long response time of the climate system, particularly the oceans. {10.3, 10.7}

Previous IPCC projections of future climate changes can now be compared to recent observations, increasing confidence in short-term projections and the underlying physical understanding of committed climate change over a few decades. Projections for 1990 to 2005 carried out for the FAR and the SAR suggested global mean temperature increases of about 0.3°C and 0.15°C per decade, respectively.[10] The difference between the two was due primarily to the inclusion of aerosol cooling effects in the SAR, whereas there was no quantitative basis for doing so in the FAR. Projections given in the TAR were similar to those of the SAR. These results are comparable to observed values of about 0.2°C per decade, as shown in Figure TS.26, providing broad confidence in such short-term projections. Some of this warming is the committed effect of changes in the concentrations of greenhouse gases prior to the times of those earlier assessments. {1.2, 3.2}

Committed climate change (see Box TS.9) due to atmospheric composition in the year 2000 corresponds to a warming trend of about 0.1°C per decade over the next two decades, in the absence of large changes in volcanic or solar forcing. About twice as much warming (0.2°C per decade) would be expected if emissions were to fall within the range of the SRES marker scenarios. This result is insensitive to the choice among the SRES marker scenarios, none of which considered climate initiatives. By 2050, the range of expected warming shows limited sensitivity to the choice among SRES scenarios (1.3°C to 1.7°C relative to 1980–1999) with about a quarter being due to the committed climate change if all radiative forcing agents were stabilised today. {10.3, 10.5, 10.7}

Sea level is expected to continue to rise over the next several decades. During 2000 to 2020 under the SRES A1B scenario in the ensemble of AOGCMs, the rate of thermal expansion is projected to be 1.3 ± 0.7 mm yr^{-1}, and is not significantly different under the A2 or B1 scenarios. These projected rates are within the uncertainty of the observed contribution of thermal expansion for 1993 to 2003 of 1.6 ± 0.6 mm yr^{-1}. The ratio of committed thermal expansion, caused by constant atmospheric composition at year 2000 values, to total thermal expansion (that is the ratio of expansion occurring after year 2000 to that occurring before and after) is larger than the corresponding ratio for global average surface temperature. {10.6, 10.7}

Box TS.9: Committed Climate Change

If the concentrations of greenhouse gases and aerosols were held fixed after a period of change, the climate system would continue to respond due to the thermal inertia of the oceans and ice sheets and their long time scales for adjustment. 'Committed warming' is defined here as the further change in global mean temperature after atmospheric composition, and hence radiative forcing, is held constant. Committed change also involves other aspects of the climate system, in particular sea level. Note that holding concentrations of radiatively active species constant would imply that ongoing emissions match natural removal rates, which for most species would be equivalent to a large reduction in emissions, although the corresponding model experiments are not intended to be considered as emission scenarios. {FAQ 10.3}

The troposphere adjusts to changes in its boundary conditions over time scales shorter than a month or so. The upper ocean responds over time scales of several years to decades, and the deep ocean and ice sheet response time scales are from centuries to millennia. When the radiative forcing changes, internal properties of the atmosphere tend to adjust quickly. However, because the atmosphere is strongly coupled to the oceanic mixed layer, which in turn is coupled to the deeper oceanic layer, it takes a very long time for the atmospheric variables to come to an equilibrium. During the long periods where the surface climate is changing very slowly, one can consider that the atmosphere is in a quasi-equilibrium state, and most energy is being absorbed by the ocean, so that ocean heat uptake is a key measure of climate change. {10.7}

[10] See IPCC First Assessment Report, Policymakers Summary, and Second Assessment Report, Technical Summary, Figure 18.

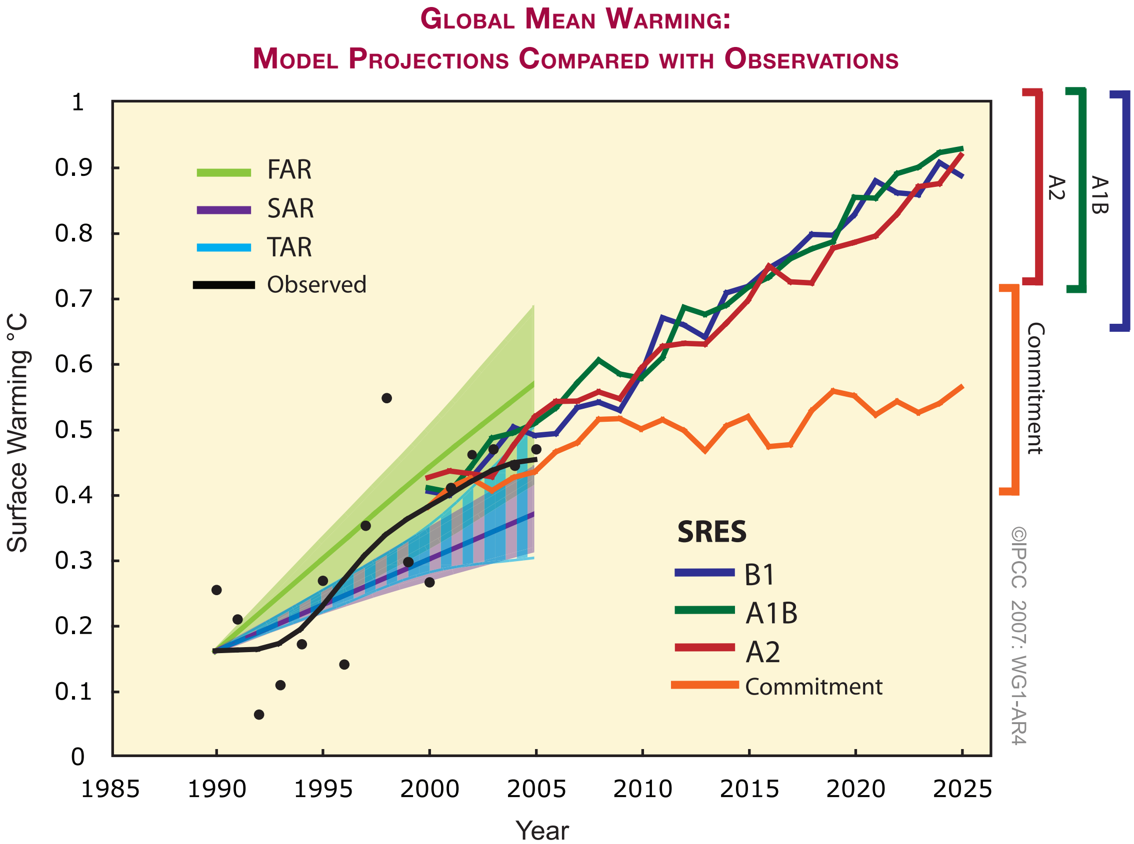

Figure TS.26. *Model projections of global mean warming compared to observed warming. Observed temperature anomalies, as in Figure TS.6, are shown as annual (black dots) and decadal average values (black line). Projected trends and their ranges from the IPCC First (FAR) and Second (SAR) Assessment Reports are shown as green and magenta solid lines and shaded areas, and the projected range from the TAR is shown by vertical blue bars. These projections were adjusted to start at the observed decadal average value in 1990. Multi-model mean projections from this report for the SRES B1, A1B and A2 scenarios, as in Figure TS.32, are shown for the period 2000 to 2025 as blue, green and red curves with uncertainty ranges indicated against the right-hand axis. The orange curve shows model projections of warming if greenhouse gas and aerosol concentrations were held constant from the year 2000 – that is, the committed warming. {Figures 1.1 and 10.4}*

TS.5.2 Large-Scale Projections for the 21st Century

This section covers advances in understanding global-scale climate projections and the processes that will influence their large-scale patterns in the 21st century. More specific discussion of regional-scale changes follows in TS.5.3.

Projected global average surface warming for the end of the 21st century (2090–2099) is scenario-dependent and the actual warming will be significantly affected by the actual emissions that occur. Warmings compared to 1980 to 1999 for six SRES scenarios[11] and for constant year 2000 concentrations, given as best estimates and corresponding *likely* ranges, are shown in Table TS.6. These results are based on AOGCMs, observational constraints and other methods to quantify the range of model response (see Figure TS.27). The combination of multiple lines of evidence allows likelihoods to be assigned to the resulting ranges, representing an important advance since the TAR. {10.5}

Assessed uncertainty ranges are larger than those given in the TAR because they consider a more complete range of models and climate-carbon cycle feedbacks. Warming tends to reduce land and ocean uptake of atmospheric CO_2, increasing the fraction of anthropogenic emissions that remains in the atmosphere. For the A2 scenario for example, the CO_2 feedback increases the corresponding global average warming in 2100 by more than 1°C. {7.3, 10.5}

[11] Approximate CO_2 equivalent concentrations corresponding to the computed radiative forcing due to anthropogenic greenhouse gases and aerosols in 2100 (see p. 823 of the TAR) for the SRES B1, A1T, B2, A1B, A2 and A1FI illustrative marker scenarios are about 600, 700, 800, 850, 1,250 and 1,550 ppm respectively. Constant emission at year 2000 levels would lead to a concentration for CO_2 alone of about 520 ppm by 2100.

Table TS.6. *Projected global average surface warming and sea level rise at the end of the 21st century. {10.5, 10.6, Table 10.7}*

Case	Temperature Change (°C at 2090-2099 relative to 1980-1999) [a] Best estimate	*Likely* range	Sea Level Rise (m at 2090-2099 relative to 1980-1999) Model-based range excluding future rapid dynamical changes in ice flow
Constant Year 2000 concentrations [b]	0.6	0.3 – 0.9	NA
B1 scenario	1.8	1.1 – 2.9	0.18 – 0.38
A1T scenario	2.4	1.4 – 3.8	0.20 – 0.45
B2 scenario	2.4	1.4 – 3.8	0.20 – 0.43
A1B scenario	2.8	1.7 – 4.4	0.21 – 0.48
A2 scenario	3.4	2.0 – 5.4	0.23 – 0.51
A1FI scenario	4.0	2.4 – 6.4	0.26 – 0.59

Notes:
[a] These estimates are assessed from a hierarchy of models that encompass a simple climate model, several Earth Models of Intermediate Complexity (EMICs), and a large number of Atmosphere-Ocean Global Circulation Models (AOGCMs).
[b] Year 2000 constant composition is derived from AOGCMs only.

Projected global-average sea level rise at the end of the 21st century (2090 to 2099), relative to 1980 to 1999 for the six SRES marker scenarios, given as 5% to 95% ranges based on the spread of model results, are shown in Table TS.6. Thermal expansion contributes 70 to 75% to the best estimate for each scenario. An improvement since the TAR is the use of AOGCMs to evaluate ocean heat uptake and thermal expansion. This has also reduced the projections as compared to the simple model used in the TAR. In all the SRES marker scenarios except B1, the average rate of sea level rise during the 21st century *very likely* exceeds the 1961–2003 average rate (1.8 ± 0.5 mm yr^{-1}). For an average model, the scenario spread in sea level rise is only 0.02 m by the middle of the century, but by the end of the century it is 0.15 m. These ranges do not include uncertainties in carbon-cycle feedbacks or ice flow processes because a basis in published literature is lacking. {10.6, 10.7}

For each scenario, the midpoint of the range given here is within 10% of the TAR model average for 2090–2099, noting that the TAR projections were given for 2100, whereas projections in this report are for 2090–2099. The uncertainty in these projections is less than in the TAR for several reasons: uncertainty in land ice models is assumed independent of uncertainty in temperature and expansion projections; improved observations of recent mass loss from glaciers provide a better observational constraint; and the present report gives uncertainties as 5% to 95% ranges, equivalent to ±1.65 standard deviations, whereas the TAR gave uncertainty ranges of ±2 standard deviations. The TAR would have had similar ranges for sea level projections to those in this report if it had treated the uncertainties in the same way. {10.6, 10.7}

Changes in the cryosphere will continue to affect sea level rise during the 21st century. Glaciers, ice caps and the Greenland Ice Sheet are projected to lose mass in the 21st century because increased melting will exceed increased snowfall. Current models suggest that the Antarctic Ice Sheet will remain too cold for widespread melting and may gain mass in future through increased snowfall, acting to reduce sea level rise. However, changes in ice dynamics could increase the contributions of both Greenland and Antarctica to 21st-century sea level rise. Recent observations of some Greenland outlet glaciers give strong evidence for enhanced flow when ice shelves are removed. The observations in west-central Greenland of seasonal variation in ice flow rate and of a correlation with summer temperature variation suggest that surface melt water may join a sub-glacially routed drainage system lubricating the ice flow. By both of these mechanisms, greater surface melting during the 21st century could cause acceleration of ice flow and discharge and increase the sea level contribution. In some parts of West Antarctica, large accelerations of ice flow have recently occurred, which may have been caused by thinning of ice shelves due to ocean warming. Although this has not been formally attributed to anthropogenic climate change due to greenhouse gases, it suggests that future warming could cause faster mass loss and greater

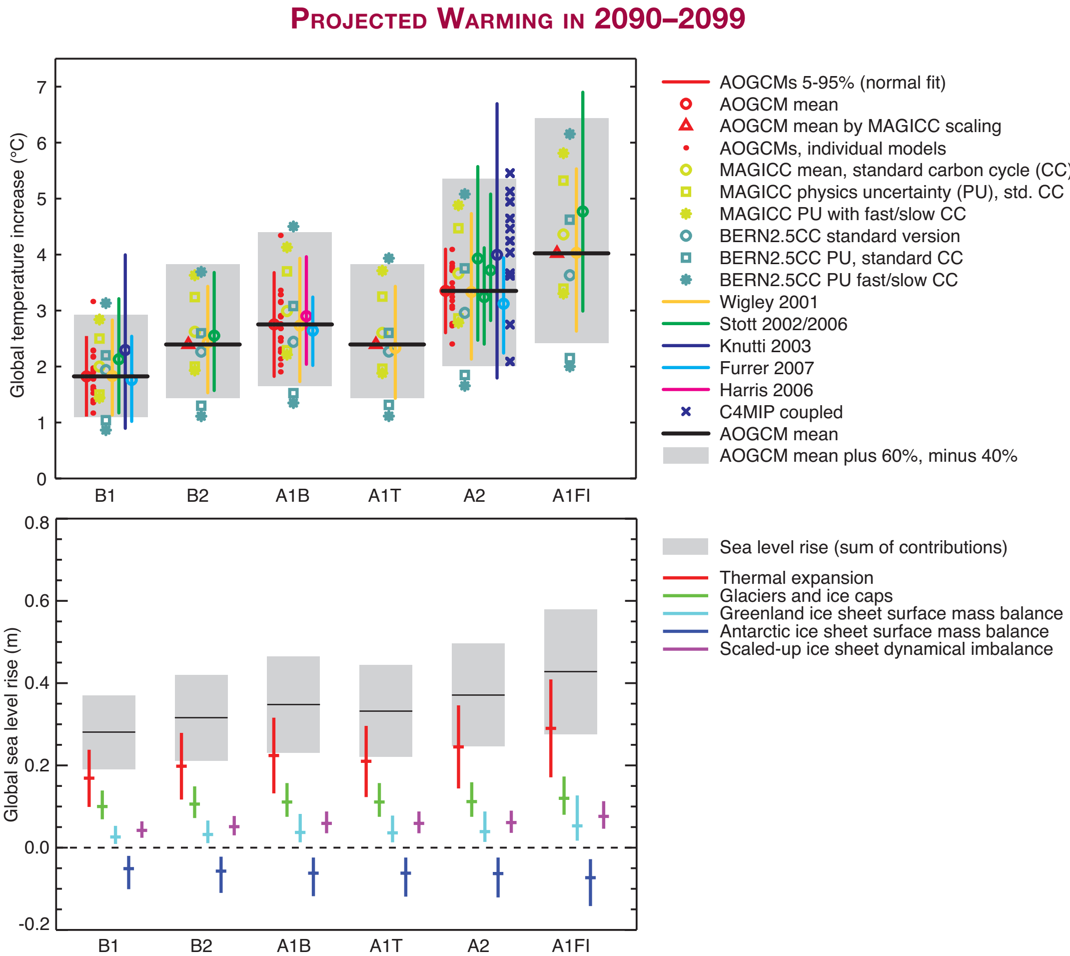

Figure TS.27. *(Top) Projected global mean temperature change in 2090 to 2099 relative to 1980 to 1999 for the six SRES marker scenarios based on results from different and independent models. The multi-model AOGCM mean and the range of the mean minus 40% to the mean plus 60% are shown as black horizontal solid lines and grey bars, respectively. Carbon cycle uncertainties are estimated for scenario A2 based on Coupled Carbon Cycle Climate Model Intercomparison Project (C⁴MIP) models (dark blue crosses), and for all marker scenarios using an EMIC (pale blue symbols). Other symbols represent individual studies (see Figure 10.29 for details of specific models). (Bottom) Projected global average sea level rise and its components in 2090 to 2099 (relative to 1980–1999) for the six SRES marker scenarios. The uncertainties denote 5 to 95% ranges, based on the spread of model results, and not including carbon cycle uncertainties. The contributions are derived by scaling AOGCM results and estimating land ice changes from temperature changes (see Appendix 10.A for details). Individual contributions are added to give the total sea level rise, which does not include the contribution shown for ice sheet dynamical imbalance, for which the current level of understanding prevents a best estimate from being given. {Figures 10.29 and 10.33}*

sea level rise. Quantitative projections of this effect cannot be made with confidence. If recently observed increases in ice discharge rates from the Greenland and Antarctic Ice Sheets were to increase linearly with global average temperature change, that would add 0.1 to 0.2 m to the upper bound of sea level rise. Understanding of these effects is too limited to assess their likelihood or to give a best estimate. {4.6, 10.6}

Many of the global and regional patterns of temperature and precipitation seen in the TAR projections remain in the new generation of models and across ensemble results (see Figure TS.28). Confidence in the robustness of these patterns is increased by the fact that they have remained largely unchanged while overall model simulations have improved (Box TS.7). This adds to confidence that these patterns reflect basic physical constraints on the climate system as it warms. {8.3–8.5, 10.3, 11.2–11.9}

The projected 21st-century temperature change is positive everywhere. It is greatest over land and at most high latitudes in the NH during winter, and increases going from the coasts into the continental interiors. In otherwise geographically similar areas, warming is typically larger in arid than in moist regions. {10.3, 11.2–11.9}

In contrast, warming is least over the southern oceans and parts of the North Atlantic Ocean. Temperatures are projected to increase, including over the North Atlantic and Europe, despite a projected slowdown of the meridional overturning circulation (MOC) in most models, due to the much larger influence of the increase in greenhouse gases. The projected pattern of zonal mean temperature change in the atmosphere displays a maximum warming in the upper tropical troposphere and cooling in the stratosphere. Further zonal mean warming in the ocean is expected to occur first near the surface and in the northern mid-latitudes, with the warming gradually reaching the ocean interior, most evident at high latitudes where vertical mixing is greatest. The projected pattern of change is very similar among the late-century cases irrespective of the scenario. Zonally averaged fields normalised by the mean warming are very similar for the scenarios examined (see Figure TS.28). {10.3}

It is *very likely* that the Atlantic MOC will slow down over the course of the 21st century. The multi-model average reduction by 2100 is 25% (range from zero to about 50%) for SRES emission scenario A1B. Temperatures in the Atlantic region are projected to increase despite such changes due to the much larger warming associated with projected increases of greenhouse gases. The projected reduction of the Atlantic MOC is due to the combined effects of an increase in high latitude temperatures and precipitation, which reduce the density of the surface waters in the North Atlantic. This could lead to a significant reduction in Labrador Sea Water formation. Very few AOGCM studies have included the impact of additional freshwater from melting of the Greenland Ice Sheet, but those that have do not suggest that this will lead to a complete MOC shutdown. Taken together, it is *very likely* that the MOC will reduce, but very *unlikely* that the MOC will undergo a large abrupt transition during the course of the 21st century. Longer-term changes in the MOC cannot be assessed with confidence. {8.7, 10.3}

Projections of Surface Temperatures

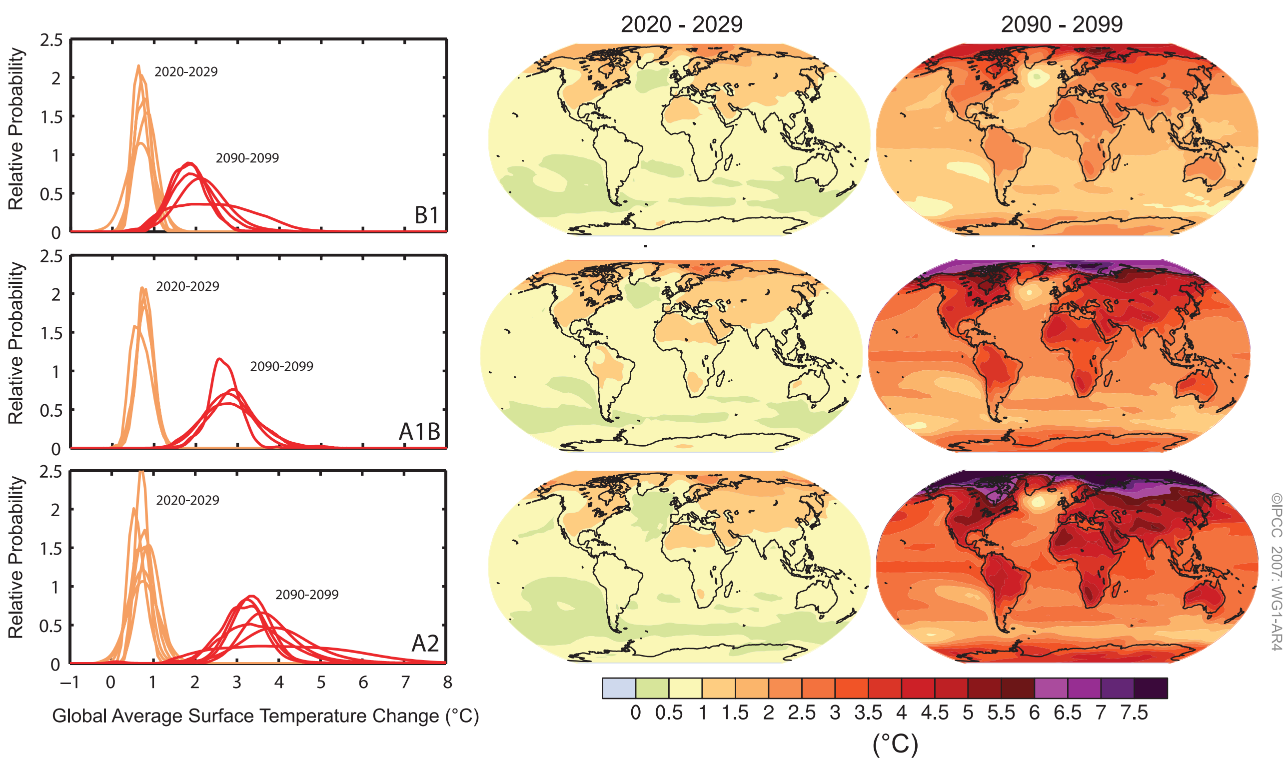

Figure TS.28. *Projected surface temperature changes for the early and late 21st century relative to the period 1980 to 1999. The central and right panels show the AOGCM multi-model average projections (°C) for the B1 (top), A1B (middle) and A2 (bottom) SRES scenarios averaged over the decades 2020 to 2029 (centre) and 2090 to 2099 (right). The left panel shows corresponding uncertainties as the relative probabilities of estimated global average warming from several different AOGCM and EMIC studies for the same periods. Some studies present results only for a subset of the SRES scenarios, or for various model versions. Therefore the difference in the number of curves, shown in the left-hand panels, is due only to differences in the availability of results. {Adapted from Figures 10.8 and 10.28}*

Models indicate that sea level rise during the 21st century will not be geographically uniform. Under scenario A1B for 2070 to 2099, AOGCMs give a median spatial standard deviation of 0.08 m, which is about 25% of the central estimate of the global average sea level rise. The geographic patterns of future sea level change arise mainly from changes in the distribution of heat and salinity in the ocean and consequent changes in ocean circulation. Projected patterns display more similarity across models than those analysed in the TAR. Common features are a smaller than average sea level rise in the Southern Ocean, larger than average sea level rise in the Arctic and a narrow band of pronounced sea level rise stretching across the southern Atlantic and Indian Oceans. {10.6}

Projections of changes in extremes such as the frequency of heat waves are better quantified than in the TAR, due to improved models and a better assessment of model spread based on multi-model ensembles. The TAR concluded that there was a risk of increased temperature extremes, with more extreme heat episodes in a future climate. This result has been confirmed and expanded in more recent studies. Future increases in temperature extremes are projected to follow increases in mean temperature over most of the world except where surface properties (e.g., snow cover or soil moisture) change. A multi-model analysis, based on simulations of 14 models for three scenarios, investigated changes in extreme seasonal (DJF and JJA) temperatures where 'extreme' is defined as lying above the 95th percentile of the simulated temperature distribution for the 20th century. By the end of the 21st century, the projected probability of extreme warm seasons rises above 90% in many tropical areas, and reaches around 40% elsewhere. Several recent studies have addressed possible future changes in heat waves, and found that, in a future climate, heat waves are expected to be more intense, longer lasting and more frequent. Based on an eight-member multi-model ensemble, heat waves are simulated to have been increasing for the latter part of the 20th century, and are projected to increase globally and over most regions. {8.5, 10.3}

For a future warmer climate, models project a 50 to 100% decline in the frequency of cold air outbreaks relative to the present in NH winters in most areas. Results from a nine-member multi-model ensemble show simulated decreases in frost days for the 20th century continuing into the 21st century globally and in most regions. Growing season length is related to frost days and is projected to increase in future climates. {10.3, FAQ 10.1}

Snow cover is projected to decrease. Widespread increases in thaw depth are projected to occur over most permafrost regions. {10.3}

Under several different scenarios (SRES A1B, A2 and B1), large parts of the Arctic Ocean are expected to no longer have year-round ice cover by the end of the 21st century. Arctic sea ice responds sensitively to warming. While projected changes in winter sea ice extent are moderate, late-summer sea ice is projected to disappear almost completely towards the end of the 21st century under the A2 scenario in some models. The reduction is accelerated by a number of positive feedbacks in the climate system. The ice-albedo feedback allows open water to receive more heat from the Sun during summer, the insulating effect of sea ice is reduced and the increase in ocean heat transport to the Arctic further reduces ice cover. Model simulations indicate that the late-summer sea ice cover decreases substantially and generally evolves over the same time scale as global warming. Antarctic sea ice extent is also projected to decrease in the 21st century. {8.6, 10.3, Box 10.1}

Sea level pressure is projected to increase over the subtropics and mid-latitudes, and decrease over high latitudes associated with an expansion of the Hadley Circulation and annular mode changes (NAM/NAO and SAM, see Box TS.2). A positive trend in the NAM/NAO as well as the SAM index is projected by many models. The magnitude of the projected increase is generally greater for the SAM, and there is considerable spread among the models. As a result of these changes, storm tracks are projected to move poleward, with consequent changes in wind, precipitation and temperature patterns outside the tropics, continuing the broad pattern of observed trends over the last half century. Some studies suggest fewer storms in mid-latitude regions. There are also indications of changes in extreme wave height associated with changing storm tracks and circulation. {3.6, 10.3}

In most models, the central and eastern equatorial Pacific SSTs warm more than those in the western equatorial Pacific, with a corresponding mean eastward shift in precipitation. ENSO interannual variability is projected to continue in all models, although changes differ from model to model. Large inter-model differences in projected changes in El Niño amplitude, and the inherent centennial time-scale variability of El Niño in the models, preclude a definitive projection of trends in ENSO variability. {10.3}

Recent studies with improved global models, ranging in resolution from about 100 to 20 km, suggest future changes in the number and intensity of future tropical cyclones (typhoons and hurricanes).

A synthesis of the model results to date indicates, for a warmer future climate, increased peak wind intensities and increased mean and peak precipitation intensities in future tropical cyclones, with the possibility of a decrease in the number of relatively weak hurricanes, and increased numbers of intense hurricanes. However, the total number of tropical cyclones globally is projected to decrease. The apparent observed increase in the proportion of very intense hurricanes since 1970 in some regions is in the same direction but much larger than predicted by theoretical models. {10.3, 8.5, 3.8}

Since the TAR, there is an improving understanding of projected patterns of precipitation. Increases in the amount of precipitation are *very likely* at high latitudes while decreases are *likely* in most subtropical land regions (by as much as about 20% in the A1B scenario in 2100). Poleward of 50°, mean precipitation is projected to increase due to the increase in water vapour in the atmosphere and the resulting increase in vapour transport from lower latitudes. Moving equatorward, there is a transition to mostly decreasing precipitation in the subtropics (20°–40° latitude). Due to increased water vapour transport out of the subtropics and a poleward expansion of the subtropical high-pressure systems, the drying tendency is especially pronounced at the higher-latitude margins of the subtropics (see Figure TS.30). {8.3, 10.3, 11.2–11.9}

Models suggest that changes in mean precipitation amount, even where robust, will rise above natural variability more slowly than the temperature signal. {10.3, 11.1}

Available research indicates a tendency for an increase in heavy daily rainfall events in many regions, including some in which the mean rainfall is projected to decrease. In the latter cases, the rainfall decrease is often attributable to a reduction in the number of rain days rather than the intensity of rain when it occurs. {11.2–11.9}

TS.5.3 Regional-Scale Projections

For each of the continental regions, the projected warming over 2000 to 2050 resulting from the SRES emissions scenarios is greater than the global average and greater than the observed warming over the past century. The warming projected for the next few decades of the 21st century, when averaged over the continents individually, would substantially exceed estimated 20th-century natural forced and unforced variability in all cases except Antarctica (Figure TS.29). Model best-estimate projections indicate that decadal average warming over each continent except Antarctica by 2030 is *very likely* to be at least twice as large as the corresponding model-estimated natural variability during the 20th century. The simulated warming over this period is not very sensitive to the choice of scenarios across the SRES set as is illustrated in Figure TS.32. Over longer time scales, the choice of scenario is more important, as shown in Figure TS.28. The projected warming in the SRES scenarios over 2000 to 2050 also exceeds estimates of natural variability when averaged over most sub-continental regions. {11.1}

Box TS.10. Regional Downscaling

Simulation of regional climates has improved in AOGCMs and, as a consequence, in nested regional climate models and in empirical downscaling techniques. Both dynamic and empirical downscaling methodologies show improving skill in simulating local features in present-day climates when the observed state of the atmosphere at scales resolved by current AOGCMs is used as input. The availability of downscaling and other regionally focused studies remains uneven geographically, causing unevenness in the assessments that can be provided, particularly for extreme weather events. Downscaling studies demonstrate that local precipitation changes can vary significantly from those expected from the large-scale hydrological response pattern, particularly in areas of complex topography. {11.10}

There remain a number of important sources of uncertainty limiting the ability to project regional climate change. While hydrological responses are relatively robust in certain core subpolar and subtropical regions, there is uncertainty in the precise location of these boundaries between increasing and decreasing precipitation. There are some important climate processes that have a significant effect on regional climate, but for which the climate change response is still poorly known. These include ENSO, the NAO, blocking, the thermohaline circulation and changes in tropical cyclone distribution. For those regions that have strong topographical controls on their climatic patterns, there is often insufficient climate change information at the fine spatial resolution of the topography. In some regions there has been only very limited research on extreme weather events. Further, the projected climate change signal becomes comparable to larger internal variability at smaller spatial and temporal scales, making it more difficult to utilise recent trends to evaluate model performance. {Box 11.1, 11.2–11.9}

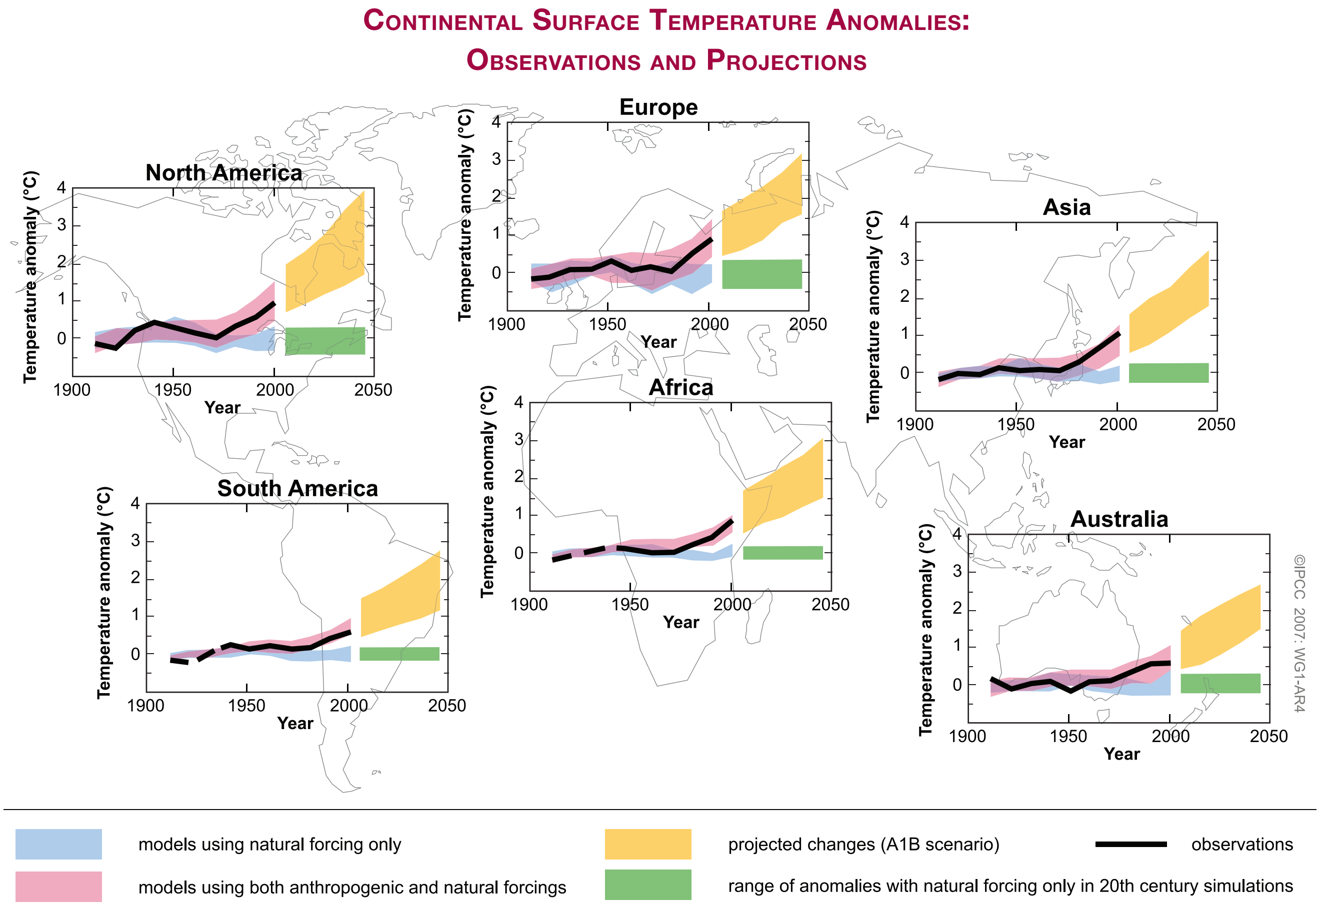

Figure TS.29. *Decadal mean continental surface temperature anomalies (°C) in observations and simulations for the period 1906 to 2005 and in projections for 2001 to 2050. Anomalies are calculated from the 1901 to 1950 average. The black lines represent the observations and the red and blue bands show simulated average temperature anomalies as in Figure TS.22 for the 20th century (i.e., red includes anthropogenic and natural forcings and blue includes only natural forcings). The yellow shading represents the 5th to 95th percentile range of projected changes according to the SRES A1B emissions scenario. The green bar denotes the 5th to 95th percentile range of decadal mean anomalies from the 20th-century simulations with only natural forcings (i.e., a measure of the natural decadal variability). For the observed part of these graphs, the decadal averages are centred on calendar decade boundaries (i.e., the last point is at 2000 for 1996 to 2005), whereas for the future period they are centred on calendar decade mid-points (i.e., the first point is at 2005 for 2001 to 2010). To construct the ranges, all simulations from the set of models involved were considered independent realisations of the possible evolution of the climate given the forcings applied. This involved 58 simulations from 14 models for the red curve, 19 simulations from 5 models (a subset of the 14) for the blue curve and green bar and 47 simulations from 18 models for the yellow curve. {FAQ 9.2.1, Figure 1 and Box 11.1, Figure 1}*

In the NH a robust pattern of increased subpolar and decreased subtropical precipitation dominates the projected precipitation pattern for the 21st century over North America and Europe, while subtropical drying is less evident over Asia (see Figure TS.30). Nearly all models project increased precipitation over most of northern North America and decreased precipitation over Central America, with much of the continental USA and northern Mexico in a more uncertain transition zone that moves north and south following the seasons. Decreased precipitation is confidently projected for southern Europe and Mediterranean Africa, with a transition to increased precipitation in northern Europe. In both continents, summer drying is extensive due both to the poleward movement of this transition zone in summer and to increased evaporation. Subpolar increases in precipitation are projected over much of northern Asia but with the subtropical drying spreading from the Mediterranean displaced by distinctive monsoonal signatures as one moves from central Asia eastward. {11.2–11.5}

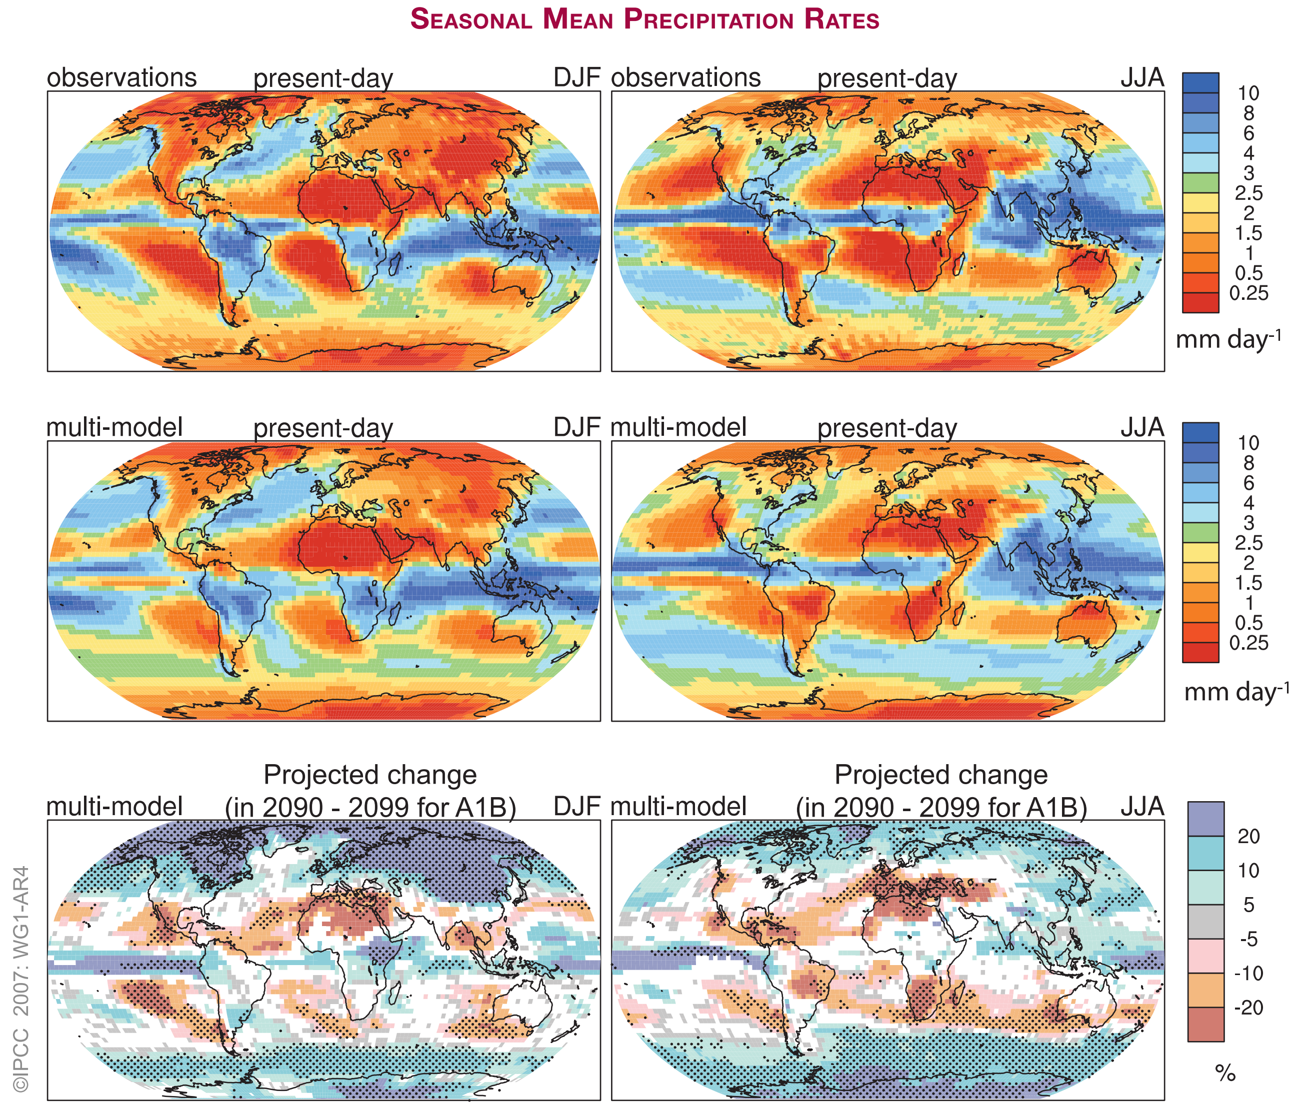

Figure TS.30. *Spatial patterns of observed (top row) and multi-model mean (middle row) seasonal mean precipitation rate (mm day^{-1}) for the period 1979 to 1993 and the multi-model mean for changes by the period 2090 to 2099 relative to 1980 to 1999 (% change) based on the SRES A1B scenario (bottom row). December to February means are in the left column, June to August means in the right column. In the bottom panel, changes are plotted only where more than 66% of the models agree on the sign of the change. The stippling indicates areas where more than 90% of the models agree on the sign of the change. {Based on same datasets as shown in Figures 8.5 and 10.9}*

In the SH, there are few land areas in the zone of projected subpolar moistening during the 21st century, with the subtropical drying more prominent (see Figure TS.30). The South Island of New Zealand and Tierra del Fuego fall within the subpolar precipitation increase zone, with southernmost Africa, the southern Andes in South America and southern Australia experiencing the drying tendency typical of the subtropics. {11.2, 11.6, 11.7}

Projections of precipitation over tropical land regions are more uncertain than those at higher latitudes, but, despite significant inadequacies in modelling tropical convection and atmosphere-ocean interactions, and the added uncertainty associated with tropical cyclones, some robust features emerge in models. Rainfall in the summer monsoon season of South and Southeast Asia increases in most models, as does rainfall in East Africa. The sign of the precipitation response is considered less certain over both the Amazon and the African Sahel. These are regions in which there is added uncertainty due to potential vegetation-climate links, and there is less robustness across models even when vegetation feedbacks are not included. {8.3, 11.2, 11.4, 11.6}

TS.5.4 Coupling Between Climate Change and Changes in Biogeochemical Cycles

All models that treat the coupling of the carbon cycle to climate change indicate a positive feedback effect with warming acting to suppress land and ocean uptake of CO_2, leading to larger atmospheric CO_2 increases and greater climate change for a given emissions scenario, but the strength of this feedback effect varies markedly among models. Since the TAR, several new projections based on fully coupled carbon cycle-climate models have been performed and compared. For the SRES A2 scenario, and based on a range of model results, the projected increase in atmospheric CO_2 concentration over the 21st century is *likely* between 10 and 25% higher than projections without this feedback, adding more than 1°C to projected mean warming by 2100 for higher emission SRES scenarios. Correspondingly, the reduced CO_2 uptake caused by this effect reduces the CO_2 emissions that are consistent with a target stabilisation level. However, there are still significant uncertainties due, for example, to limitations in the understanding of the dynamics of land ecosystems and soils. {7.3, 10.4}

Increasing atmospheric CO_2 concentrations lead directly to increasing acidification of the surface ocean. Projections based on SRES scenarios give reductions in pH of between 0.14 and 0.35 units in the 21st century (depending on scenario), extending the present decrease of 0.1 units from pre-industrial times. Ocean acidification would lead to dissolution of shallow-water carbonate sediments. Southern Ocean surface waters are projected to exhibit undersaturation with regard to calcium carbonate ($CaCO_3$) for CO_2 concentrations higher than 600 ppm, a level exceeded during the second half of the 21st century in most of the SRES scenarios. Low-latitude regions and the deep ocean will be affected as well. These changes could affect marine organisms that form their exoskeletons out of $CaCO_3$, but the net effect on the biological cycling of carbon in the oceans is not well understood. {Box 7.3, 10.4}

Committed climate change due to past emissions varies considerably for different forcing agents because of differing lifetimes in the Earth's atmosphere (see Box TS.9). The committed climate change due to past emissions takes account of both (i) the time lags in the responses of the climate system to changes in radiative forcing; and (ii) the time scales over which different forcing agents persist in the atmosphere after their emission because of their differing lifetimes. Typically the committed climate change due to past emissions includes an initial period of further increase in temperature, for the reasons discussed above, followed by a long-term decrease as radiative forcing decreases. Some greenhouse gases have relatively short atmospheric lifetimes (decades or less), such as CH_4 and carbon monoxide, while others such as N_2O have lifetimes of the order of a century, and some have lifetimes of millennia, such as SF_6 and PFCs. Atmospheric concentrations of CO_2 do not decay with a single well-defined lifetime if emissions are stopped. Removal of CO_2 emitted to the atmosphere occurs over multiple time scales, but some CO_2 will stay in the atmosphere for many thousands of years, so that emissions lead to a very long commitment to climate change. The slow long-term buffering of the ocean, including $CaCO_3$-sediment feedback, requires 30,000 to 35,000 years for atmospheric CO_2 concentrations to reach equilibrium. Using coupled carbon cycle components, EMICs show that the committed climate change due to past CO_2 emissions persists for more than 1000 years, so that even over these very long time scales, temperature and sea level do not return to pre-industrial values. An indication of the long time scales of committed climate change is obtained by prescribing anthropogenic CO_2 emissions following a path towards stabilisation at 750 ppm, but arbitrarily setting emissions to zero at year 2100. In this test case, it takes about 100 to 400 years in the different models for the atmospheric CO_2 concentration to drop from the maximum (ranges between 650 to 700 ppm) to below the level of two times the pre-industrial CO_2 concentration (about 560 ppm), owing to a continuous but slow transfer of carbon from the atmosphere and terrestrial reservoirs to the ocean (see Figure TS.31). {7.3, 10.7}

Future concentrations of many non-CO_2 greenhouse gases and their precursors are expected to be coupled to future climate change. Insufficient understanding of the causes of recent variations in the CH_4 growth rate suggests large uncertainties in future projections for this gas in particular. Emissions of CH_4 from wetlands are *likely* to increase in a warmer and wetter climate and to decrease in a warmer and drier climate. Observations also suggest increases in CH_4 released from northern peatlands that are experiencing permafrost melt, although the large-scale magnitude of this effect is not well quantified. Changes in temperature, humidity and clouds could also affect biogenic emissions of ozone precursors, such as volatile organic compounds. Climate change is also expected to affect tropospheric ozone through changes in chemistry and transport. Climate change could induce changes in OH through changes in humidity, and could alter stratospheric ozone concentrations and hence solar ultraviolet radiation in the troposphere. {7.4, 4.7}

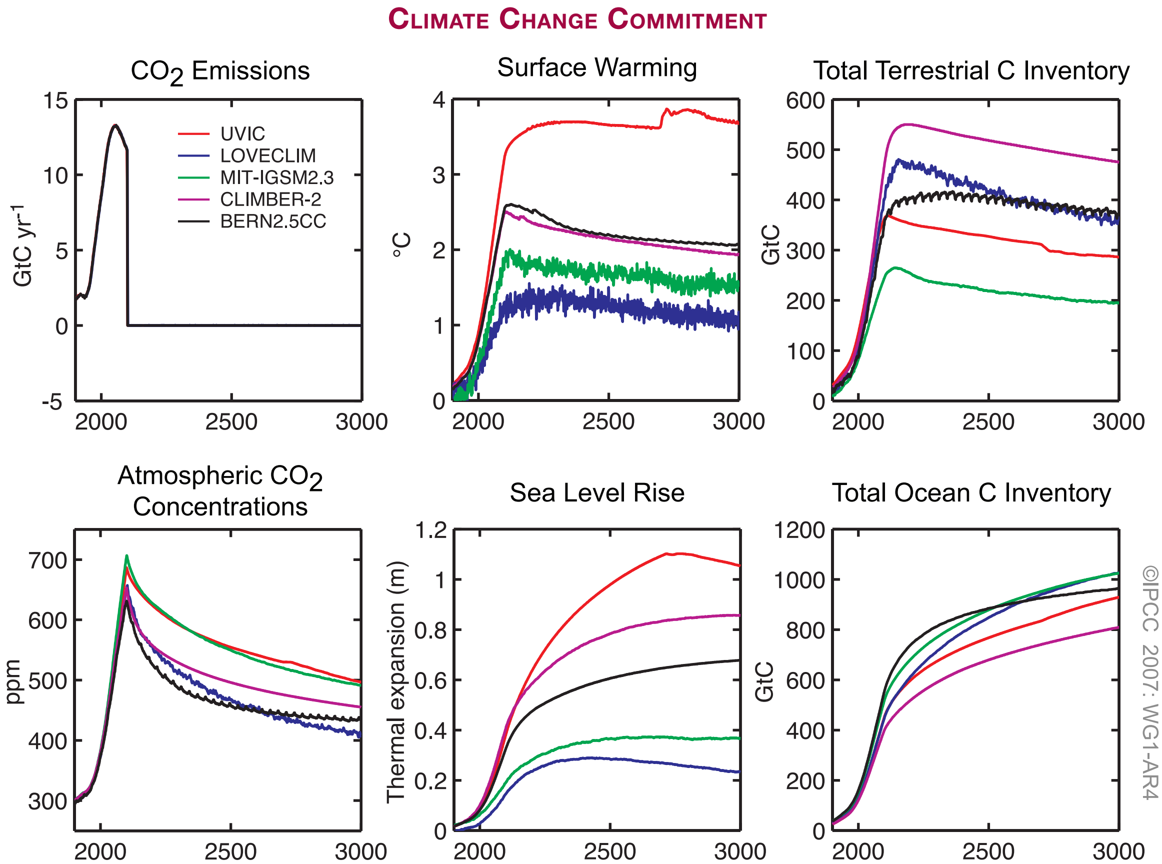

Figure TS.31. *Calculation of climate change commitment due to past emissions for five different EMICs and an idealised scenario where emissions follow a pathway leading to stabilisation of atmospheric CO_2 at 750 ppm, but before reaching this target, emissions are reduced to zero instantly at year 2100. (Left) CO_2 emissions and atmospheric CO_2 concentrations; (centre) surface warming and sea level rise due to thermal expansion; (right) change in total terrestrial and oceanic carbon inventory since the pre-industrial era. {Figure 10.35}*

Future emissions of many aerosols and their precursors are expected to be affected by climate change. Estimates of future changes in dust emissions under several climate and land use scenarios suggest that the effects of climate change are more important in controlling future dust emissions than changes in land use. Results from one study suggest that meteorology and climate have a greater influence on future Asian dust emissions and associated Asian dust storm occurrences than desertification. The biogenic emission of volatile organic compounds, a significant source of secondary organic aerosols, is known to be highly sensitive to (and increase with) temperature. However, aerosol yields decrease with temperature and the effects of changing precipitation and physiological adaptation are uncertain. Thus, change in biogenic secondary organic aerosol production in a warmer climate could be considerably lower than the response of biogenic volatile organic carbon emissions. Climate change may affect fluxes from the ocean of dimethyl sulphide (which is a precursor for some sulphate aerosols) and sea salt aerosols, however, the effects on temperature and precipitation remain very uncertain. {7.5}

While the warming effect of CO_2 represents a commitment over many centuries, aerosols are removed from the atmosphere over time scales of only a few days, so that the negative radiative forcing due to aerosols could change rapidly in response to any changes in emissions of aerosols or aerosol precursors. Because sulphate aerosols are *very likely* exerting a substantial negative radiative forcing at present, future net forcing is very sensitive to changes in sulphate emissions. One study suggests that the hypothetical removal from the atmosphere of the entire current burden of anthropogenic sulphate aerosol particles would produce a rapid increase in global mean temperature of about 0.8°C within a decade or two. Changes in aerosols are also likely to influence precipitation. Thus, the effect of environmental strategies aimed at mitigating climate change requires consideration of changes in both greenhouse gas and aerosol emissions.

Changes in aerosol emissions may result from measures implemented to improve air quality which may therefore have consequences for climate change. {Box 7.4, 7.6, 10.7}

Climate change would modify a number of chemical and physical processes that control air quality and the net effects are *likely* to vary from one region to another. Climate change can affect air quality by modifying the rates at which pollutants are dispersed, the rate at which aerosols and soluble species are removed from the atmosphere, the general chemical environment for pollutant generation and the strength of emissions from the biosphere, fires and dust. Climate change is also expected to decrease the global ozone background. Overall, the net effect of climate change on air quality is highly uncertain. {Box 7.4}

TS.5.5 Implications of Climate Processes and their Time Scales for Long-Term Projections

The commitments to climate change after stabilisation of radiative forcing are expected to be about 0.5 to 0.6°C, mostly within the following century. The multi-model average when stabilising concentrations of greenhouse gases and aerosols at year 2000 values after a 20th-century climate simulation, and running an additional 100 years, is about 0.6°C of warming (relative to 1980–1999) at year 2100 (see Figure TS.32). If the B1 or A1B scenarios were to characterise 21st-century emissions followed by stabilisation at those levels, the additional warming after stabilisation is similar, about 0.5°C, mostly in the subsequent hundred years. {10.3, 10.7}

The magnitude of the positive feedback between climate change and the carbon cycle is uncertain. This leads to uncertainty in the trajectory of CO_2 emissions required to achieve a particular stabilization level of atmospheric CO_2 concentration. Based upon current understanding of climate-carbon cycle feedback, model studies suggest that, in order to stabilise CO_2 at 450 ppm, cumulative emissions in the 21st century could be reduced from a model average of approximately 670 [630 to 710] GtC to approximately 490 [375 to 600] GtC. Similarly, to stabilise CO_2 at 1000 ppm, the cumulative emissions could be reduced by this feedback from a model average of

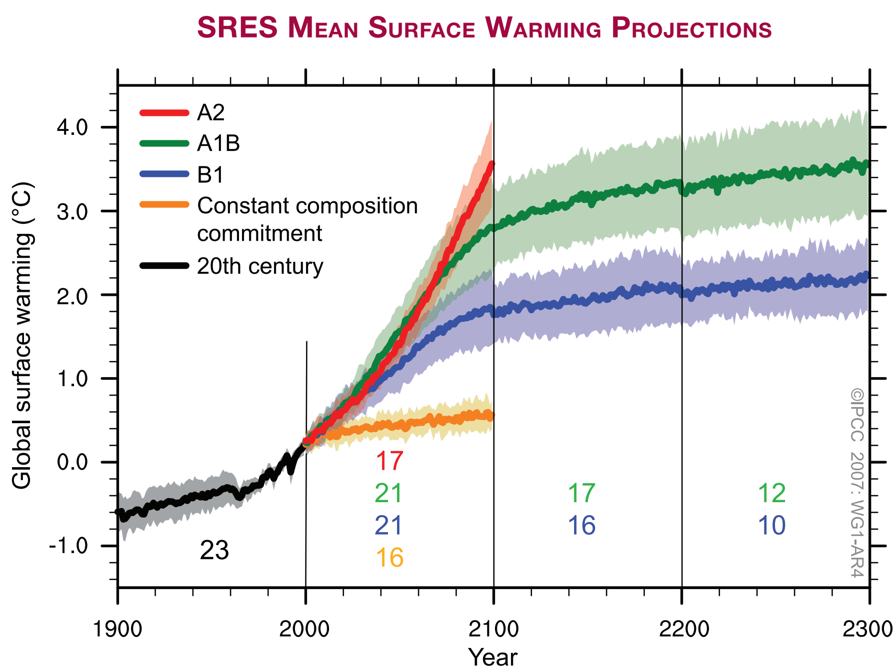

Figure TS.32. *Multi-model means of surface warming (compared to the 1980–1999 base period) for the SRES scenarios A2 (red), A1B (green) and B1 (blue), shown as continuations of the 20th-century simulation. The latter two scenarios are continued beyond the year 2100 with forcing kept constant (committed climate change as it is defined in Box TS.9). An additional experiment, in which the forcing is kept at the year 2000 level is also shown (orange). Linear trends from the corresponding control runs have been removed from these time series. Lines show the multi-model means, shading denotes the ±1 standard deviation range. Discontinuities between different periods have no physical meaning and are caused by the fact that the number of models that have run a given scenario is different for each period and scenario (numbers indicated in figure). For the same reason, uncertainty across scenarios should not be interpreted from this figure (see Section 10.5 for uncertainty estimates). {Figure 10.4}* approximately 1415 [1340 to 1490] GtC to approximately 1100 [980 to 1250] GtC. {7.3, 10.4}

If radiative forcing were to be stabilised in 2100 at A1B concentrations, thermal expansion alone would lead to 0.3 to 0.8 m of sea level rise by 2300 (relative to 1980–1999) and would continue at decreasing rates for many centuries, due to slow processes that mix heat into the deep ocean. {10.7}

Contraction of the Greenland Ice Sheet is projected to continue to contribute to sea level rise after 2100. For stabilisation at A1B concentrations in 2100, a rate of 0.03 to 0.21 m per century due to thermal expansion is projected. If a global average warming of 1.9°C to 4.6°C relative to pre-industrial temperatures were maintained for millennia, the Greenland Ice Sheet would largely be eliminated except for remnant glaciers in the mountains. This would raise sea level by about 7 m and could be irreversible. These temperatures are comparable to those inferred for the last interglacial period 125,000 years ago, when palaeoclimatic information suggests reductions of polar ice extent and 4 to 6 m of sea level rise. {6.4, 10.7}

Dynamical processes not included in current models but suggested by recent observations could increase the vulnerability of the ice sheets to warming, increasing future sea level rise. Understanding of these processes is limited and there is no consensus on their likely magnitude. {4.6, 10.7}

Current global model studies project that the Antarctic Ice Sheet will remain too cold for widespread surface melting and will gain in mass due to increased snowfall. However, net loss of ice mass could occur if dynamical ice discharge dominates the ice sheet mass balance. {10.7}

While no models run for this assessment suggest an abrupt MOC shutdown during the 21st century, some models of reduced complexity suggest MOC shutdown as a possible long-term response to sufficiently strong warming. However, the likelihood of this occurring cannot be evaluated with confidence. The few available simulations with models of different complexity rather suggest a centennial-scale slowdown. Recovery of the MOC is *likely* if the radiative forcing is stabilised but would take several centuries. Systematic model comparison studies have helped establish some key processes that are responsible for variations between models in the response of the ocean to climate change (especially ocean heat uptake). {8.7, FAQ 10.2, 10.3}

TS.6 Robust Findings and Key Uncertainties

TS.6.1 Changes in Human and Natural Drivers of Climate

Robust Findings:

Current atmospheric concentrations of CO_2 and CH_4, and their associated positive radiative forcing, far exceed those determined from ice core measurements spanning the last 650,000 years. {6.4}

Fossil fuel use, agriculture and land use have been the dominant cause of increases in greenhouse gases over the last 250 years. {2.3, 7.3, 7.4}

Annual emissions of CO_2 from fossil fuel burning, cement production and gas flaring increased from a mean of 6.4 ± 0.4 GtC yr^{-1} in the 1990s to 7.2 ± 0.3 GtC yr^{-1} for 2000 to 2005. {7.3}

The sustained rate of increase in radiative forcing from CO_2, CH_4 and N_2O over the past 40 years is larger than at any time during at least the past 2000 years. {6.4}

Natural processes of CO_2 uptake by the oceans and terrestrial biosphere remove about 50 to 60% of anthropogenic emissions (i.e., fossil CO_2 emissions and land use change flux). Uptake by the oceans and the terrestrial biosphere are similar in magnitude over recent decades but that by the terrestrial biosphere is more variable. {7.3}

It is *virtually certain* that anthropogenic aerosols produce a net negative radiative forcing (cooling influence) with a greater magnitude in the NH than in the SH. {2.9, 9.2}

From new estimates of the combined anthropogenic forcing due to greenhouse gases, aerosols and land surface changes, it is *extremely likely* that human activities have exerted a substantial net warming influence on climate since 1750. {2.9}

Solar irradiance contributions to global average radiative forcing are considerably smaller than the contribution of increases in greenhouse gases over the industrial period. {2.5, 2.7}

Key Uncertainties:

The full range of processes leading to modification of cloud properties by aerosols is not well understood and the magnitudes of associated indirect radiative effects are poorly determined. {2.4, 7.5}

The causes of, and radiative forcing due to stratospheric water vapour changes are not well quantified. {2.3}

The geographical distribution and time evolution of the radiative forcing due to changes in aerosols during the 20th century are not well characterised. {2.4}

The causes of recent changes in the growth rate of atmospheric CH_4 are not well understood. {7.4}

The roles of different factors increasing tropospheric ozone concentrations since pre-industrial times are not well characterised. {2.3}

Land surface properties and land-atmosphere interactions that lead to radiative forcing are not well quantified. {2.5}

Knowledge of the contribution of past solar changes to radiative forcing on the time scale of centuries is not based upon direct measurements and is hence strongly dependent upon physical understanding. {2.7}

TS.6.2 Observations of Changes in Climate

TS.6.2.1 Atmosphere and Surface

Robust Findings:

Global mean surface temperatures continue to rise. Eleven of the last 12 years rank among the 12 warmest years on record since 1850. {3.2}

Rates of surface warming increased in the mid-1970s and the global land surface has been warming at about double the rate of ocean surface warming since then. {3.2}

Changes in surface temperature extremes are consistent with warming of the climate. {3.8}

Estimates of mid- and lower-tropospheric temperature trends have substantially improved. Lower-tropospheric temperatures have slightly greater warming rates than the surface from 1958 to 2005. {3.4}

Long-term trends from 1900 to 2005 have been observed in precipitation amount in many large regions. {3.3}

Increases have occurred in the number of heavy precipitation events. {3.8}

Droughts have become more common, especially in the tropics and subtropics, since the 1970s. {3.3}

Tropospheric water vapour has increased, at least since the 1980s. {3.4}

Key Uncertainties:

Radiosonde records are much less complete spatially than surface records and evidence suggests a number of radiosonde records are unreliable, especially in the tropics. It is likely that all records of tropospheric temperature trends still contain residual errors. {3.4}

While changes in large-scale atmospheric circulation are apparent, the quality of analyses is best only after 1979, making analysis of, and discrimination between, change and variability difficult. {3.5, 3.6}

Surface and satellite observations disagree on total and low-level cloud changes over the ocean. {3.4}

Multi-decadal changes in DTR are not well understood, in part because of limited observations of changes in cloudiness and aerosols. {3.2}

Difficulties in the measurement of precipitation remain an area of concern in quantifying trends in global and regional precipitation. {3.3}

Records of soil moisture and streamflow are often very short, and are available for only a few regions, which impedes complete analyses of changes in droughts. {3.3}

The availability of observational data restricts the types of extremes that can be analysed. The rarer the event, the more difficult it is to identify long-term changes because there are fewer cases available. {3.8}

Information on hurricane frequency and intensity is limited prior to the satellite era. There are questions about the interpretation of the satellite record. {3.8}

There is insufficient evidence to determine whether trends exist in tornadoes, hail, lightning and dust storms at small spatial scales. {3.8}

TS.6.2.2 Snow, Ice and Frozen Ground

Robust Findings:

The amount of ice on the Earth is decreasing. There has been widespread retreat of mountain glaciers since the end of the 19th century. The rate of mass loss from glaciers and the Greenland Ice Sheet is increasing. {4.5, 4.6}

The extent of NH snow cover has declined. Seasonal river and lake ice duration has decreased over the past 150 years. {4.2, 4.3}

Since 1978, annual mean arctic sea ice extent has been declining and summer minimum arctic ice extent has decreased. {4.4}

Ice thinning occurred in the Antarctic Peninsula and Amundsen shelf ice during the 1990s. Tributary glaciers have accelerated and complete breakup of the Larsen B Ice Shelf occurred in 2002. {4.6}

Temperature at the top of the permafrost layer has increased by up to 3°C since the 1980s in the Arctic. The maximum extent of seasonally frozen ground has decreased by about 7% in the NH since 1900, and its maximum depth has decreased by about 0.3 m in Eurasia since the mid-20th century. {4.7}

Key Uncertainties:

There is no global compilation of *in situ* snow data prior to 1960. Well-calibrated snow water equivalent data are not available for the satellite era. {4.2}

There are insufficient data to draw any conclusions about trends in the thickness of antarctic sea ice. {4.4}

Uncertainties in estimates of glacier mass loss arise from limited global inventory data, incomplete area-volume relationships and imbalance in geographic coverage. {4.5}

Mass balance estimates for ice shelves and ice sheets, especially for Antarctica, are limited by calibration and validation of changes detected by satellite altimetry and gravity measurements. {4.6}

Limited knowledge of basal processes and of ice shelf dynamics leads to large uncertainties in the understanding of ice flow processes and ice sheet stability. {4.6}

TS.6.2.3 Oceans and Sea Level

Robust Findings:

The global temperature (or heat content) of the oceans has increased since 1955. {5.2}

Large-scale regionally coherent trends in salinity have been observed over recent decades with freshening in subpolar regions and increased salinity in the shallower parts of the tropics and subtropics. These trends are consistent with changes in precipitation and inferred larger water transport in the atmosphere from low latitudes to high latitudes and from the Atlantic to the Pacific. {5.2}

Global average sea level rose during the 20th century. There is high confidence that the rate of sea level rise increased between the mid-19th and mid-20th centuries. During 1993 to 2003, sea level rose more rapidly than during 1961 to 2003. {5.5}

Thermal expansion of the ocean and loss of mass from glaciers and ice caps made substantial contributions to the observed sea level rise. {5.5}

The observed rate of sea level rise from 1993 to 2003 is consistent with the sum of observed contributions from thermal expansion and loss of land ice. {5.5}

The rate of sea level change over recent decades has not been geographically uniform. {5.5}

As a result of uptake of anthropogenic CO_2 since 1750, the acidity of the surface ocean has increased. {5.4, 7.3}

Key Uncertainties:

Limitations in ocean sampling imply that decadal variability in global heat content, salinity and sea level changes can only be evaluated with moderate confidence. {5.2, 5.5}

There is low confidence in observations of trends in the MOC. {Box 5.1}

Global average sea level rise from 1961 to 2003 appears to be larger than can be explained by thermal expansion and land ice melting. {5.5}

TS.6.2.4 Palaeoclimate

Robust Findings:

During the last interglacial, about 125,000 years ago, global sea level was *likely* 4 to 6 m higher than present, due primarily to retreat of polar ice. {6.4}

A number of past abrupt climate changes were *very likely* linked to changes in Atlantic Ocean circulation and affected the climate broadly across the NH. {6.4}

It is *very unlikely* that the Earth would naturally enter another ice age for at least 30,000 years. {6.4}

Biogeochemical and biogeophysical feedbacks have amplified climatic changes in the past. {6.4}

It is *very likely* that average NH temperatures during the second half of the 20th century were warmer than in any other 50-year period in the last 500 years and *likely* that this was also the warmest 50-year period in the past 1300 years. {6.6}

Palaeoclimate records indicate with high confidence that droughts lasting decades or longer were a recurrent feature of climate in several regions over the last 2000 years. {6.6}

Key Uncertainties:

Mechanisms of onset and evolution of past abrupt climate change and associated climate thresholds are not well understood. This limits confidence in the ability of climate models to simulate realistic abrupt change. {6.4}

The degree to which ice sheets retreated in the past, the rates of such change and the processes involved are not well known. {6.4}

Knowledge of climate variability over more than the last few hundred years in the SH and tropics is limited by the lack of palaeoclimatic records. {6.6}

Differing amplitudes and variability observed in available millennial-length NH temperature reconstructions, as well as the relation of these differences to choice of proxy data and statistical calibration methods, still need to be reconciled. {6.6}

The lack of extensive networks of proxy data for temperature in the last 20 years limits understanding of how such proxies respond to rapid global warming and of the influence of other environmental changes. {6.6}

TS.6.3 Understanding and Attributing Climate Change

Robust Findings:

Greenhouse gas forcing has *very likely* caused most of the observed global warming over the last 50 years. Greenhouse gas forcing alone during the past half century would *likely* have resulted in greater than the observed warming if there had not been an offsetting cooling effect from aerosol and other forcings. {9.4}

It is *extremely unlikely* (<5%) that the global pattern of warming during the past half century can be explained without external forcing, and *very unlikely* that it is due to known natural external causes alone. The warming occurred in both the ocean and the atmosphere and took place at a time when natural external forcing factors would *likely* have produced cooling. {9.4, 9.7}

It is *likely* that anthropogenic forcing has contributed to the general warming observed in the upper several hundred metres of the ocean during the latter half of the 20th century. Anthropogenic forcing, resulting in thermal expansion from ocean warming and glacier mass loss, has *very likely* contributed to sea level rise during the latter half of the 20th century. {9.5}

A substantial fraction of the reconstructed NH inter-decadal temperature variability of the past seven centuries is *very likely* attributable to natural external forcing (volcanic eruptions and solar variability). {9.3}

Key Uncertainties:

Confidence in attributing some climate change phenomena to anthropogenic influences is currently limited by uncertainties in radiative forcing, as well as uncertainties in feedbacks and in observations. {9.4, 9.5}

Attribution at scales smaller than continental and over time scales of less than 50 years is limited by larger climate variability on smaller scales, by uncertainties in the small-scale details of external forcing and the response simulated by models, as well as uncertainties in simulation of internal variability on small scales, including in relation to modes of variability. {9.4}

There is less confidence in understanding of forced changes in precipitation and surface pressure than there is of temperature. {9.5}

The range of attribution statements is limited by the absence of formal detection and attribution studies, or their very limited number, for some phenomena (e.g., some types of extreme events). {9.5}

Incomplete global data sets for extremes analysis and model uncertainties still restrict the regions and types of detection studies of extremes that can be performed. {9.4, 9.5}

Despite improved understanding, uncertainties in model-simulated internal climate variability limit some aspects of attribution studies. For example, there are apparent discrepancies between estimates of ocean heat content variability from models and observations. {5.2, 9.5}

Lack of studies quantifying the contributions of anthropogenic forcing to ocean heat content increase or glacier melting together with the open part of the sea level budget for 1961 to 2003 are among the uncertainties in quantifying the anthropogenic contribution to sea level rise. {9.5}

TS.6.4 Projections of Future Changes in Climate

TS.6.4.1 Model Evaluation

Robust Findings:

Climate models are based on well-established physical principles and have been demonstrated to reproduce observed features of recent climate and past climate changes. There is considerable confidence that AOGCMs provide credible quantitative estimates of future climate change, particularly at continental scales and above. Confidence in these estimates is higher for some climate variables (e.g., temperature) than for others (e.g., precipitation). {FAQ 8.1}

Confidence in models has increased due to:

- improvements in the simulation of many aspects of present climate, including important modes of climate variability and extreme hot and cold spells;
- improved model resolution, computational methods and parametrizations and inclusion of additional processes;
- more comprehensive diagnostic tests, including tests of model ability to forecast on time scales from days to a year when initialised with observed conditions; and
- enhanced scrutiny of models and expanded diagnostic analysis of model behaviour facilitated by internationally coordinated efforts to collect and disseminate output from model experiments performed under common conditions. {8.4}

Key Uncertainties:

A proven set of model metrics comparing simulations with observations, that might be used to narrow the range of plausible climate projections, has yet to be developed. {8.2}

Most models continue to have difficulty controlling climate drift, particularly in the deep ocean. This drift must be accounted for when assessing change in many oceanic variables. {8.2}

Models differ considerably in their estimates of the strength of different feedbacks in the climate system. {8.6}

Problems remain in the simulation of some modes of variability, notably the Madden-Julian Oscillation, recurrent atmospheric blocking and extreme precipitation. {8.4}

Systematic biases have been found in most models' simulations of the Southern Ocean that are linked to uncertainty in transient climate response. {8.3}

Climate models remain limited by the spatial resolution that can be achieved with present computer resources, by the need for more extensive ensemble runs and by the need to include some additional processes. {8.1–8.5}

TS.6.4.2 Equilibrium and Transient Climate Sensitivity

Robust Findings:

Equilibrium climate sensitivity is *likely* to be in the range 2°C to 4.5°C with a most likely value of about 3°C, based upon multiple observational and modelling constraints. It is *very unlikely* to be less than 1.5°C. {8.6, 9.6, Box 10.2}

The transient climate response is better constrained than the equilibrium climate sensitivity. It is *very likely* larger than 1°C and *very unlikely* greater than 3°C. {10.5}

There is a good understanding of the origin of differences in equilibrium climate sensitivity found in different models. Cloud feedbacks are the primary source of inter-model differences in equilibrium climate sensitivity, with low cloud being the largest contributor. {8.6}

New observational and modelling evidence strongly supports a combined water vapour-lapse rate feedback of a strength comparable to that found in AOGCMs. {8.6}

Key Uncertainties:

Large uncertainties remain about how clouds might respond to global climate change. {8.6}

TS.6.4.3 Global Projections

Robust Findings:

Even if concentrations of radiative forcing agents were to be stabilised, further committed warming and related climate changes would be expected to occur, largely because of time lags associated with processes in the oceans. {10.7}

Near-term warming projections are little affected by different scenario assumptions or different model sensitivities, and are consistent with that observed for the past few decades. The multi-model mean warming, averaged over 2011 to 2030 relative to 1980 to 1999 for all AOGCMs considered here, lies in a narrow range of 0.64°C to 0.69°C for the three different SRES emission scenarios B1, A1B and A2. {10.3}

Geographic patterns of projected warming show the greatest temperature increases at high northern latitudes and over land, with less warming over the southern oceans and North Atlantic. {10.3}

Changes in precipitation show robust large-scale patterns: precipitation generally increases in the tropical precipitation maxima, decreases in the subtropics and increases at high latitudes as a consequence of a general intensification of the global hydrological cycle. {10.3}

As the climate warms, snow cover and sea ice extent decrease; glaciers and ice caps lose mass and contribute to sea level rise. Sea ice extent decreases in the 21st century in both the Arctic and Antarctic. Snow cover reduction is accelerated in the Arctic by positive feedbacks and widespread increases in thaw depth occur over much of the permafrost regions. {10.3}

Based on current simulations, it is *very likely* that the Atlantic Ocean MOC will slow down by 2100. However, it is *very unlikely* that the MOC will undergo a large abrupt transition during the course of the 21st century. {10.3}

Heat waves become more frequent and longer lasting in a future warmer climate. Decreases in frost days are projected to occur almost everywhere in the mid- and high latitudes, with an increase in growing season length. There is a tendency for summer drying of the mid-continental areas during summer, indicating a greater risk of droughts in those regions. {10.3, FAQ 10.1}

Future warming would tend to reduce the capacity of the Earth system (land and ocean) to absorb anthropogenic CO_2. As a result, an increasingly large fraction of anthropogenic CO_2 would stay in the atmosphere under a warmer climate. This feedback requires reductions in the cumulative emissions consistent with stabilisation at a given atmospheric CO_2 level compared to the hypothetical case of no such feedback. The higher the stabilisation scenario, the larger the amount of climate change and the larger the required reductions. {7.3, 10.4}

Key Uncertainties:

The likelihood of a large abrupt change in the MOC beyond the end of the 21st century cannot yet be assessed reliably. For low and medium emission scenarios with atmospheric greenhouse gas concentrations stabilised beyond 2100, the MOC recovers from initial weakening within one to several centuries. A permanent reduction in the MOC cannot be excluded if the forcing is strong and long enough. {10.7}

The model projections for extremes of precipitation show larger ranges in amplitude and geographical locations than for temperature. {10.3, 11.1}

The response of some major modes of climate variability such as ENSO still differs from model to model, which may be associated with differences in the spatial and temporal representation of present-day conditions. {10.3}

The robustness of many model responses of tropical cyclones to climate change is still limited by the resolution of typical climate models. {10.3}

Changes in key processes that drive some global and regional climate changes are poorly known (e.g., ENSO, NAO, blocking, MOC, land surface feedbacks, tropical cyclone distribution). {11.2–11.9}

The magnitude of future carbon cycle feedbacks is still poorly determined. {7.3, 10.4}

TS.6.4.4 Sea Level

Robust Findings:

Sea level will continue to rise in the 21st century because of thermal expansion and loss of land ice. Sea level rise was not geographically uniform in the past and will not be in the future. {10.6}

Projected warming due to emission of greenhouse gases during the 21st century will continue to contribute to sea level rise for many centuries. {10.7}

Sea level rise due to thermal expansion and loss of mass from ice sheets would continue for centuries or millennia even if radiative forcing were to be stabilised. {10.7}

Key Uncertainties:

Models do not yet exist that address key processes that could contribute to large rapid dynamical changes in the Antarctic and Greenland Ice Sheets that could increase the discharge of ice into the ocean. {10.6}

The sensitivity of ice sheet surface mass balance (melting and precipitation) to global climate change is not well constrained by observations and has a large spread in models. There is consequently a large uncertainty in the magnitude of global warming that, if sustained, would lead to the elimination of the Greenland Ice Sheet. {10.7}

TS.6.4.5 Regional Projections

Robust Findings:

Temperatures averaged over all habitable continents and over many sub-continental land regions will *very likely* rise at greater than the global average rate in the next 50 years and by an amount substantially in excess of natural variability. {10.3, 11.2–11.9}

Precipitation is *likely* to increase in most subpolar and polar regions. The increase is considered especially robust, and *very likely* to occur, in annual precipitation in most of northern Europe, Canada, the northeast USA and the Arctic, and in winter precipitation in northern Asia and the Tibetan Plateau. {11.2–11.9}

Precipitation is *likely* to decrease in many subtropical regions, especially at the poleward margins of the subtropics. The decrease is considered especially robust, and *very likely* to occur, in annual precipitation in European and African regions bordering the Mediterranean and in winter rainfall in south-western Australia. {11.2–11.9}

Extremes of daily precipitation are *likely* to increase in many regions. The increase is considered as *very likely* in northern Europe, south Asia, East Asia, Australia and New Zealand – this list in part reflecting uneven geographic coverage in existing published research. {11.2–11.9}

Key Uncertainties:

In some regions there has been only very limited study of key aspects of regional climate change, particularly with regard to extreme events. {11.2–11.9}

Atmosphere-Ocean General Circulation Models show no consistency in simulated regional precipitation change in some key regions (e.g., northern South America, northern Australia and the Sahel). {10.3, 11.2–11.9}

In many regions where fine spatial scales in climate are generated by topography, there is insufficient information on how climate change will be expressed at these scales. {11.2–11.9}

Climate Change 2007: Synthesis Report

Summary for Policymakers

An Assessment of the Intergovernmental Panel on Climate Change

This summary, approved in detail at IPCC Plenary XXVII (Valencia, Spain, 12-17 November 2007), represents the formally agreed statement of the IPCC concerning key findings and uncertainties contained in the Working Group contributions to the Fourth Assessment Report.

Based on a draft prepared by:

Lenny Bernstein, Peter Bosch, Osvaldo Canziani, Zhenlin Chen, Renate Christ, Ogunlade Davidson, William Hare, Saleemul Huq, David Karoly, Vladimir Kattsov, Zbigniew Kundzewicz, Jian Liu, Ulrike Lohmann, Martin Manning, Taroh Matsuno, Bettina Menne, Bert Metz, Monirul Mirza, Neville Nicholls, Leonard Nurse, Rajendra Pachauri, Jean Palutikof, Martin Parry, Dahe Qin, Nijavalli Ravindranath, Andy Reisinger, Jiawen Ren, Keywan Riahi, Cynthia Rosenzweig, Matilde Rusticucci, Stephen Schneider, Youba Sokona, Susan Solomon, Peter Stott, Ronald Stouffer, Taishi Sugiyama, Rob Swart, Dennis Tirpak, Coleen Vogel, Gary Yohe

2. Causes of change

Changes in atmospheric concentrations of greenhouse gases (GHGs) and aerosols, land cover and solar radiation alter the energy balance of the climate system. *{2.2}*

Global GHG emissions due to human activities have grown since pre-industrial times, with an increase of 70% between 1970 and 2004 (Figure SPM.3).[5] *{2.1}*

Carbon dioxide (CO_2) is the most important anthropogenic GHG. Its annual emissions grew by about 80% between 1970 and 2004. The long-term trend of declining CO_2 emissions per unit of energy supplied reversed after 2000. *{2.1}*

Global atmospheric concentrations of CO_2, methane (CH_4) and nitrous oxide (N_2O) have increased markedly as a result of human activities since 1750 and now far exceed pre-industrial values determined from ice cores spanning many thousands of years. *{2.2}*

Atmospheric concentrations of CO_2 (379ppm) and CH_4 (1774ppb) in 2005 exceed by far the natural range over the last 650,000 years. Global increases in CO_2 concentrations are due primarily to fossil fuel use, with land-use change providing another significant but smaller contribution. It is *very likely* that the observed increase in CH_4 concentration is predominantly due to agriculture and fossil fuel use. CH_4 growth rates have declined since the early 1990s, consistent with total emissions (sum of anthropogenic and natural sources) being nearly constant during this period. The increase in N_2O concentration is primarily due to agriculture. *{2.2}*

There is *very high confidence* that the net effect of human activities since 1750 has been one of warming.[6] *{2.2}*

Most of the observed increase in global average temperatures since the mid-20th century is *very likely* due to the observed increase in anthropogenic GHG concentrations.[7] It is *likely* that there has been significant anthropogenic warming over the past 50 years averaged over each continent (except Antarctica) (Figure SPM.4). *{2.4}*

During the past 50 years, the sum of solar and volcanic forcings would *likely* have produced cooling. Observed patterns of warming and their changes are simulated only by models that include anthropogenic forcings. Difficulties remain in simulating and attributing observed temperature changes at smaller than continental scales. *{2.4}*

Global anthropogenic GHG emissions

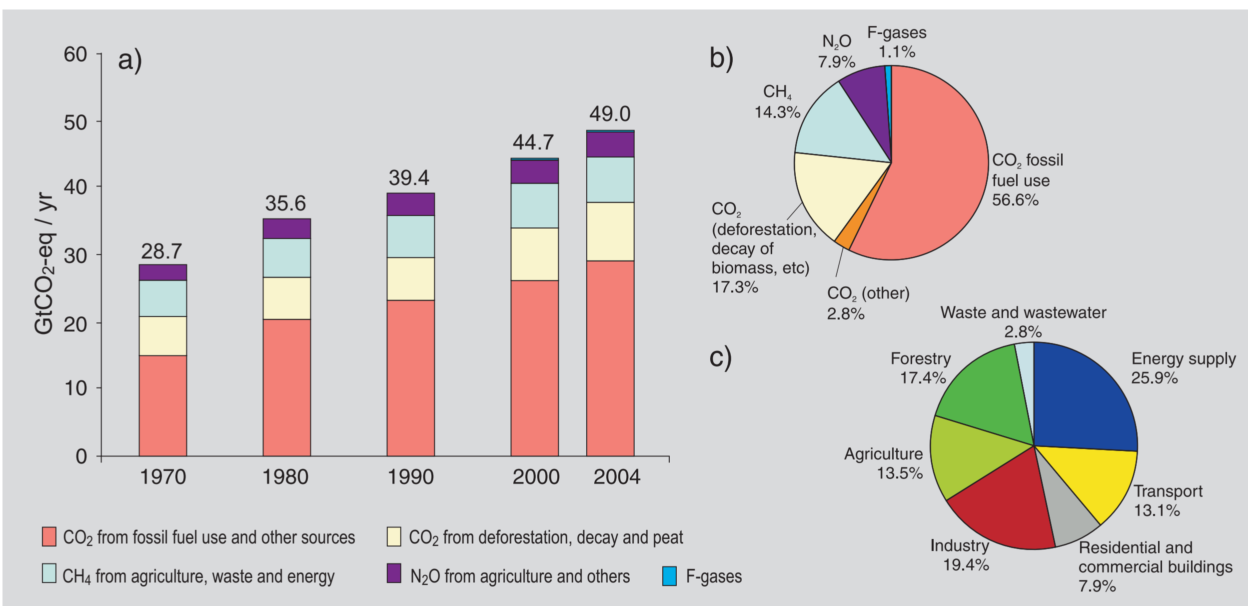

Figure SPM.3. *(a) Global annual emissions of anthropogenic GHGs from 1970 to 2004.[5] (b) Share of different anthropogenic GHGs in total emissions in 2004 in terms of carbon dioxide equivalents (CO_2-eq). (c) Share of different sectors in total anthropogenic GHG emissions in 2004 in terms of CO_2-eq. (Forestry includes deforestation.) {Figure 2.1}*

[5] Includes only carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs) and sulphurhexafluoride (SF_6), whose emissions are covered by the United Nations Framework Convention on Climate Change (UNFCCC). These GHGs are weighted by their 100-year Global Warming Potentials, using values consistent with reporting under the UNFCCC.

[6] Increases in GHGs tend to warm the surface while the net effect of increases in aerosols tends to cool it. The net effect due to human activities since the pre-industrial era is one of warming (+1.6 [+0.6 to +2.4] W/m^2). In comparison, changes in solar irradiance are estimated to have caused a small warming effect (+0.12 [+0.06 to +0.30] W/m^2).

[7] Consideration of remaining uncertainty is based on current methodologies.

For each piece of equipment selected, URBEMIS generates an emission estimate. The emission equation used by URBEMIS for each piece of equipment is as follows:

Equipment Emissions (pounds/day) = # of pieces of equipment * grams per brake horsepower-hour * equipment horsepower * hours/day * load factor

Where: ***grams per brake-horsepower hour is based on the construction year and represents a statewide average for each piece of equipment. Grams per brake horsepower per hour emissions are based on the California Air Resources Board's OFFROAD2007 model (California Air Resources Board, 2006). The pounds per day emission factors are found in Appendix I.***

Demolition Worker Commute Trips

Demolition worker commute trips assume that the number of workers equals 125% of the total pieces of construction equipment selected. The emission estimates assume a construction worker commute fleet mix of 50% light duty autos and 50% light duty trucks. The worker commute travel distance, speed, and temperature are based on the worker commute speed information included in the Operational Trip Characteristics screen.

The Costs and Financial Benefits of Green Buildings

A Report to California's
Sustainable Building Task Force

October 2003

Principal Author: Greg Kats, Capital E

Contributing Authors:
Leon Alevantis, Department of Health Services
Adam Berman, Capital E
Evan Mills, Lawrence Berkeley National Laboratory
Jeff Perlman, Capital E

This report was developed for the Sustainable Building Task Force, a group of over 40 California state government agencies. Funding for this study was provided by the Air Resources Board (ARB), California Integrated Waste Management Board CIWMB), Department of Finance (DOF), Department of General Services (DGS), Department of Transportation (Caltrans), Department of Water Resources (DWR), and Division of the State Architect (DSA). This collaborative effort was made possible through the contributions of Capital E, Future Resources Associates, Task Force members, and the United States Green Building Council.

October 3, 2003

Dear Colleagues,

This study, *The Costs and Financial Benefits of Green Building,* represents the most definitive cost benefit analysis of green building ever conducted. It demonstrates conclusively that sustainable building is a cost-effective investment, and its findings should encourage communities across the country to "build green."

In August 2000, Governor Davis issued Executive Order D-16-00, establishing sustainable building as a primary goal for state construction and tasking the State and Consumer Services Agency with its implementation. Our agency established the Sustainable Building Task Force, a unique partnership among more than 40 governmental agencies, whose combined building, environmental, and fiscal expertise has produced outstanding results, including funding for this report.

Since its inception, the Sustainable Building Task Force has worked diligently to incorporate green building principles into California's capital outlay process. Our many successes include:

- Building the first LEED Gold state owned office building in the country, the Education Headquarters Building, which is saving taxpayers $500,000 a year in energy costs alone;
- Including sustainable building performance standards, such as energy efficiency, in over $2 billion of state construction and renovation contracts;
- Constructing many high visibility state "leadership buildings," which are models of sustainability, including the Caltrans District 7 Office building in Los Angeles;
- Promoting on-site renewable energy, such as the installation of over an acre of photovoltaic panels on the roof of the Franchise Tax Board Building in Rancho Cordova – which is the largest array on any state office building in the country;
- Assisting the Chancellor of the new 10th University of California campus, UC Merced, in her goal to construct the greenest campus in the country with an initial target of LEED Silver for all construction;
- Impacting the sustainability of K-12 bond funded school construction throughout the state by providing funding and technical assistance to support the work of the Collaborative for High Performance Schools (CHPS), including the construction of 13 demonstration high performance schools; and
- Confirming through rigorous emissions testing that the careful selection of building materials in concert with environmentally responsive cleaning practices results in cleaner and healthier indoor environments.

While the environmental and human health benefits of green building have been widely recognized, this comprehensive report confirms that minimal increases in upfront costs of about 2% to support green design would, on average, result in life cycle savings of 20% of total construction costs -- more than ten times the initial investment. For example, an initial upfront investment of up to $100,000 to incorporate green building features into a $5 million project would result in a savings of $1 million in today's dollars over the life of the building. These findings clearly support the work of the Sustainable Building Task Force and reinforce our commitment to build the greenest state facilities possible.

This report was funded by several Sustainable Building Task Force member agencies, including the Air Resources Board, the Department of Finance, the Department of General Services, the Department of Transportation, the Department of Water Resources, the Division of the State Architect, and the Integrated Waste Management Board. Their resources and staff support have helped to increase our collective knowledge of the true costs and benefits of green building. In addition, I would like to recognize the contributions of Undersecretary Arnold Sowell and Senior Consultant Amanda Eichel of the State and Consumer Services Agency. Their leadership, as well as their commitment to this subject, made this project possible.

With the signing of Executive Order D-16-00 by Governor Davis, California embarked on a road to sustainability. Since that time many cities, counties, and school districts, as well as the Board of Regents for the University of California, have established similar sustainable building goals. It is extremely rewarding not only to note the major accomplishments of this Task Force, including this first of a kind study documenting the cost-effectiveness of green building, but also to witness the national impact of these extraordinary interagency efforts.

Best regards,

Aileen Adams
Secretary

TABLE OF CONTENTS

Executive Summary

Integrating "sustainable" or "green" building practices into the construction of state buildings is a solid financial investment. In the most comprehensive analysis of the financial costs and benefits of green building conducted to date, this report finds that a minimal upfront investment of about two percent of construction costs typically yields life cycle savings of over ten times the initial investment. For example, an initial upfront investment of up to $100,000 to incorporate green building features into a $5 million project would result in a savings of at least $1 million over the life of the building, assumed conservatively to be 20 years.[1]

The financial benefits of green buildings include lower energy, waste disposal, and water costs, lower environmental and emissions costs, lower operations and maintenance costs, and savings from increased productivity and health. These benefits range from being fairly predictable (energy, waste, and water savings) to relatively uncertain (productivity/health benefits). Energy and water savings can be predicted with reasonable precision, measured, and monitored over time. In contrast, productivity and health gains are much less precisely understood and far harder to predict with accuracy.

There is now a very large body of research, reviewed in this report, which demonstrates significant and causal correlation between improvements in building comfort and control measures, and worker health and productivity. However, these studies vary widely in specific measured correlations. Further, there has been relatively little work completed to evaluate specific, measurable benefits from green building design in California. Clearly, the benefits are significant and not zero, but the data supports a broad range of calculated benefits – in contrast to the more precisely measurable energy, water, and waste savings.

The financial benefits conclusions in this report should therefore be understood in this context. Energy, waste, and water savings as well as emissions reductions can be viewed as fairly precise, reasonably conservative estimates of direct benefits that alone significantly exceed the marginal cost of building green. Health and productivity benefits can be viewed as reasonably conservative estimates within a large range of uncertainty. Further research is necessary to better quantify and capture the precise savings associated with these benefits. Additional studies might include such measures as evaluating green building effects on insured and uninsured health effects, employee turnover, worker well being and, where relevant (e.g. in schools), test scores.

Background

"Green" or "sustainable" buildings use key resources like energy, water, materials, and land much more efficiently than buildings that are simply built to code. They also create healthier work, learning, and living environments, with more natural light and cleaner air, and contribute to improved employee and student health, comfort, and productivity. Sustainable buildings are cost-effective, saving taxpayer dollars by reducing operations and maintenance costs, as well as by lowering utility bills.

---

[1] Although this report was written with specific regard to California state buildings, data is national in scope and conclusions are broadly applicable to other types of buildings and for other public and private sector entities.

Over the last few years, the green building movement has gained tremendous momentum. The United States Green Building Council (USGBC), a national non-profit organization, has grown dramatically in membership. The USGBC's Leadership in Energy and Environmental Design (LEED) rating system has been widely embraced both nationally and internationally as the green building design standard. Public and private sector entities, including the cities of Santa Monica, San Diego, San Francisco, San Jose, Long Beach, Los Angeles, Seattle, and Portland; San Mateo County; the University of California; the Department of the Navy; the federal General Services Administration; and the states of Oregon, New York and Maryland have all adopted green building policies and clean energy standards. In addition, corporate entities, including Steelcase, Herman Miller, Johnson Controls, Interface, IBM, PNC Financial Services, Southern California Gas Company, Toyota, and Ford Motor Company, have constructed green buildings.

Recognizing the tremendous opportunity for California state government to provide leadership in the area of exemplary building design and construction methods, several years ago Governor Davis issued two Executive Orders that address the siting and building of state facilities:

- Executive Order D-16-00 establishes the Governor's sustainable building goal: "to site, design, deconstruct, construct, renovate, operate, and maintain state buildings that are models of energy, water, and materials efficiency; while providing healthy, productive and comfortable indoor environments and long-term benefits to Californians...The objectives are to implement the sustainable building goal in a cost effective manner…; use extended life cycle costing; and adopt an integrated systems approach.[2]"
- Executive Order D-46-01 provides guidance on the process the Department of General Services will use to locate and lease space, including such considerations as proximity to public transit and affordable housing, preserving structures of historic, cultural, and architectural significance, opportunities for economic renewal; and sensitivity to neighborhood and community concerns.[3]

The Issue of Cost

To implement the Executive Orders, the Secretary of the State and Consumer Services Agency, Aileen Adams, formally convened an interagency Sustainable Building Task Force (Task Force) comprised of over 40 state agencies, including representatives with energy, environmental, fiscal, construction, property management, and historic preservation expertise. As the Task Force set about its implementation work, the uncertainty about the "cost" of green buildings became an issue of growing importance and increased discussions.

While there seems to be consensus on the environmental and social benefits of green building, there is a consistent concern, both within and outside the green building community, over the lack of accurate and thorough financial and economic information. Recognizing that the cost issue was becoming more and more of a prohibitive factor in the mainstreaming of green building not only within California but across the country, several members of the Task Force funded an Economic Analysis Project to determine more definitively the costs and benefits of sustainable

building.[4] Sustainable buildings generally incur a "green premium" above the costs of standard construction. They also provide an array of financial and environmental benefits that conventional buildings do not. These benefits, such as energy savings, should be looked at through a life cycle cost methodology, not just evaluated in terms of upfront costs. From a life cycle savings standpoint, savings resulting from investment in sustainable design and construction dramatically exceed any additional upfront costs.

It is generally recognized that buildings consume a large portion of water, wood, energy, and other resources used in the economy. Green buildings provide a potentially promising way to help address a range of challenges facing California, such as:

- The high cost of electric power.
- Worsening electric grid constraints, with associated power quality and availability problems.
- Pending water shortage and waste disposal issues.
- Continued state and federal pressure to cut criteria pollutants.
- Growing concern over the cost of global warming.
- The rising incidence of allergies and asthma, especially in children.
- The health and productivity of workers.
- The effect of the physical school environment on children's abilities to learn.
- Increasing expenses of maintaining and operating state facilities over time.

Benefits include some elements that are relatively easy to quantify, such as energy and water savings, as well as those that are less easily quantified, such as the use of recycled content materials and improved indoor environmental quality. Prior to this report, no comprehensive analysis of the actual costs and financial benefits of green buildings had been completed, although there are a number of studies that do begin to address this very important issue.

- In October 2002, the David and Lucille Packard Foundation released their Sustainability Matrix and Sustainability Report, developed to consider environmental goals for a new 90,000 square foot office facility. The study found that with each increasing level of sustainability (including various levels of LEED), short-term costs increased, but long-term costs decreased dramatically.[5]

- A second, older study conducted by Xenergy for the City of Portland identified a 15% lifecycle savings associated with bringing three standard buildings up to USGBC LEED certification levels (with primary opportunities to save money associated with energy efficiency, water efficiency and use of salvaged materials).[6]

---

[4] Funding agencies include the Air Resources Board (ARB), California Integrated Waste Management Board (CIWMB), Department of Finance (DOF), Department of General Services (DGS), Department of Transportation (CalTrans) Department of Water Resources (DWR), and Division of the State Architect (DSA).

[6] "Green City Buildings: Applying the LEED Rating System," prepared for the Portland Energy Office by Xenergy, Inc and SERA Architects, June 18, 2000. Available at: http://www.sustainableportland.org/CityLEED.pdf.

In addition, a number of other studies document measurable benefits for enhanced daylighting, natural ventilation, and improved indoor air quality in buildings. Benefits associated with these "green" features include enhanced worker and student productivity, as well as reduced absenteeism and illness.

For example:

- One study performed by the Heschong-Mahone group looked at students in three cities and found that students in classrooms with the greatest amount of daylighting performed up to 20% better than those in classrooms that had little daylight.[7]
- A study at Herman-Miller showed up to a 7% increase in worker productivity following a move to a green, daylit facility.[8]
- A Lawrence Berkeley National Laboratory study found that U.S. businesses could save as much as $58 billion in lost sick time and an additional $200 billion in worker performance if improvements were made to indoor air quality.[9]

Report Methodology and Format

This report is the first of its kind to fully aggregate the costs and benefits of green buildings. Specifically, the bulk of this report reviews and analyzes a large quantity of existing data about the costs and financial benefits of green buildings in California. Several dozen building representatives and architects were contacted to secure the cost of 33 green buildings compared to conventional designs for those buildings. The average premium for these green buildings is slightly less than 2% (or $3-5/ ft^2, see *Implications for California,* pg.18), substantially lower than is commonly perceived. The majority of this cost is due to the increased architectural and engineering (A&E) design time necessary to integrate sustainable building practices into projects. Generally, the earlier green building gets incorporated into the design process, the lower the cost.

A literature review conducted for this report revealed that there is sufficient data from which to construct reasonable estimates about the value of many green building attributes. Historically, both private firms and public agencies do not recognize the full financial value of green buildings. They usually acknowledge some benefits from lower energy and water use, but completely ignore or critically undervalue other, often significant, financial benefits of green buildings during the design and construction decision-making process.[10] For most of these benefits, such as emissions reductions and employee productivity, there are multiple methods that can be used to derive values of benefits, as well as a large range of values that can be assigned to them. In most cases, there is no single "right" answer. Nonetheless, the report underscores that based on the body of

[10] See, for example "CEC Environmental Performance Report." Available at: http://www.energy.ca.gov/reports/2001-11-20_700-01-001.PDF. 2003 EPR will be finalized and available in October 2003 as part of the *Integrated Energy Policy Report*.

existing data, it is possible to determine reasonable, conservative estimates of financial benefits for a range of green building attributes.

The report also reveals the need for further research and analysis. In all areas, consistently conservative assumptions were made in view of data limitations. Additional research will help to refine cost and benefit estimates and likely lead to increased financial benefit calculations for green building. Additionally, throughout the report, the reader is directed to online databases and publications for the most accurate and relevant information. In many instances, these referenced documents are available online, and URLs are provided in the footnotes.

Conclusion

The benefits of building green include cost savings from reduced energy, water, and waste; lower operations and maintenance costs; and enhanced occupant productivity and health. As Figure ES-1 shows, analysis of these areas indicates that total financial benefits of green buildings are over ten times the average initial investment required to design and construct a green building. Energy savings alone exceed the average increased cost associated with building green.

Additionally, the relatively large impact of productivity and health gains reflects the fact that the direct and indirect cost of employees is far larger than the cost of construction or energy. Consequently, even small changes in productivity and health translate into large financial benefits.

Figure ES-1. Financial Benefits of Green Buildings Summary of Findings (per ft^2)

Category	20-year NPV
Energy Value	$5.79
Emissions Value	$1.18
Water Value	$0.51
Waste Value (construction only) - 1 year	$0.03
Commissioning O&M Value	$8.47
Productivity and Health Value (Certified and Silver)	$36.89
Productivity and Health Value (Gold and Platinum)	$55.33
Less Green Cost Premium	($4.00)
Total 20-year NPV (Certified and Silver)	**$48.87**
Total 20-year NPV (Gold and Platinum)	**$67.31**

Source: Capital E Analysis

Despite data limitations and the need for additional research in various areas, the findings of this report point to a clear conclusion: building green is cost-effective and makes financial sense today.

Acknowledgements

Fifty members of the Sustainable Building Task Force provided guidance and significant staff and research time to shape this work. The leadership of Arnie Sowell, Undersecretary of the California State and Consumer Services Agency, made this report possible. Amanda Eichel, Senior consultant with the California State and Consumer Agency, provided invaluable research and organizational support.

The US Green Building Council served as a partner in this effort, providing critical data, insights and support throughout the project.

Principal author Greg Kats serves as Chair of the Energy and Atmosphere Technical Advisory Group for LEED and serves on LEED's steering committee.[11]

Other members of the Capital E team - Hank Habicht, Jim Rogers and Joe Romm - provided valuable insights, edits and support.

Vivian Loftness and the Carnegie Mellon University's Department of Architecture provided invaluable information and data on the productivity benefits from improved indoor air quality.

A group of California and national leaders served on the Green Building Valuation Advisory Group, and provided invaluable guidance and information throughout the project.

I. Overview of Project

In September 2002, California's Sustainable Buildings Task Force (SBTF)[12] – composed of representatives from over 40 state agencies – with funding from seven of its constituent agencies,[13] hired a team, lead by Capital E, to undertake an economic analysis project to aid in the effort to evaluate the cost and benefits of sustainable building.

This report is intended to provide immediately useful analytic support for making informed and cost-effective building design decisions. Identification of gaps and recommendations for additional research are mentioned throughout the text and compiled in Section XII – Recommended Next Steps. These are intended to provide guidance to the SBTF in identifying opportunities to further improve understanding of the full costs and benefits of green buildings.

What is a Green Building?

"Green" or "sustainable" buildings are sensitive to:

- Environment.
- Resource & energy consumption.
- Impact on people (quality and healthiness of work environment).
- Financial impact (cost-effectiveness from a full financial cost-return perspective).
- The world at large (a broader set of issues, such as ground water recharge and global warming, that a government is typically concerned about).

California's Executive Order D-16-00 establishes a solid set of sustainable building objectives: "to site, design, deconstruct, construct, renovate, operate, and maintain state buildings that are models of energy, water and materials efficiency; while providing healthy, productive and comfortable indoor environments and long-term benefits to Californians." [14] This green building Executive Order requires consideration of externalities, economic and environmental performance measures, life cycle costing, and a whole building integrated systems approach when making sustainable building funding decisions. These objectives for sustainable building design include not only tangible savings associated with energy, water and waste efficiencies, but also "softer" benefits, such as human health and productivity, impact on the environment and incorporation of recycled content materials.

---

[12] See: http://www.ciwmb.ca.gov/GreenBuilding/TaskForce/, State of California Sustainable Building Task Force website.

[13] The seven CA state agencies that funded this study are the California Air Resources Board (ARB), California Integrated Waste Management Board (CIWMB), Department of Finance (DOF), Department of General Services (DGS), Department of Transportation (Caltrans), Department of Water Resources (DWR), and Division of the State Architect (DSA).

[14] State of California, Governor's Executive Order D-16-00. August 2000. Available at: http://www.governor.ca.gov/state/govsite/gov_homepage.jsp.
The goals of sustainable building practice in California, according to one recent article, are to: a) enhance indoor air quality; b) improve occupant health and productivity; c) increase the efficiency of material, energy, and water resource usage; and d) reduce the environmental impacts associated with the production of raw materials and the construction, deconstruction and long-term operation of buildings. Alevantis et al., "Sustainable Building Practices in California State Buildings," *Proceedings of Indoor Air 2002: The 9th International Conference on Indoor Air Quality and Climate*. Monterey, CA, June 30 – July 5, 2002. Vol. 3, pp. 666-671, Indoor Air 2002, Inc. Available at: http://www.indoorair2002.org.

In December 2001, the SBTF released the report, *Building Better Buildings: A Blueprint for Sustainable State Facilities*,[15] the first in a series of reports that will document the progress of California state government in implementing the Governor's sustainable building goals. The Blueprint notes that sustainable buildings are often called green or high performance buildings. The US Green Building Council (USGBC)[16] uses the term "green" to define a building with the same objectives as those described in the *Blueprint*. Other initiatives, such as New York's High Performance Building Design Guidelines,[17] use the term "high performance" to describe virtually the same set of building characteristics. The High Performance Guidelines draw particular attention to the use of advanced technology, or "smart infrastructure," and its impact on tenant ability to control key building comfort measures (such as temperature and light levels) to increase performance.[18]

This report will use the terms "sustainable" and "green" synonymously and interchangeably.

Sustainable design practices have been applied in American buildings for millennia, as evidenced in the exquisite structures of the Hopi Indians a thousand years ago. However, the term sustainable or green architecture as a modern, integrated design philosophy appears to be very recent. The first references to "green architecture" and "green building label" reportedly appeared in the British publication *The Independent* in London in early 1990, followed by the first American use of the term "green architecture" in mid-1990, on the editor's page of *Architecture* magazine.[19] The American Institute of Architect's Committee on the Environment started in 1989.[20] In 1991, the city of Austin established the first green building program in the United States[21] – there are now dozens of such programs nationally.[22] The Green Building committee of the American Society for Testing and Materials (ASTM) also formed in 1991.[23] Thus, the modern green building movement appears to be little over a decade old. It is therefore impressive that there is already an emerging national consensus on the definition of a green building and a rapidly increasing number of green projects in both the public and private sectors.

While there is no exactly "correct" weighting of green attributes, there is a broad consensus both with regard to the general attributes that constitute greenness, as well as the approximate

weighting that these different attributes should receive.[24] However, the definition of a sustainable building is innately subjective. There is no universally accepted way to compare such diverse green attributes as, for example, improved human health, reduced water pollution and reduced forest cutting. Different green building programs balance various dimensions of "greenness" through a necessarily subjective weighting. For example, Green Globes, a US online assessment tool for benchmarking the greenness of building performance, attributes 34% of the weighting of building greenness to energy use, more than the USGBC's Leadership in Energy and Environmental Design (LEED) Rating System's 29%.[25] Because of the wide range of "green" attributes considered, no single scientific denominator exists, and weighting reflects consensus best judgment rather than scientific determination.

The range of definitions of what constitutes a green or sustainable building includes:

- The British Research Establishment Environmental Assessment Method (BREEAM) was launched in 1990 and is increasing in use.[26]
- Canada's Building Environmental Performance Assessment Criteria (BEPAC) began in 1994.[27] This system was never fully implemented due to its complexity.
- The Hong Kong Building Environmental Assessment Method (HK-BEAM) is currently in pilot form.[28]
- The US Green Building Council (established in 1993) began development of the Leadership in Environmental and Energy Design (LEED) Green Building Rating System™ in 1994. Version 2.0 of the LEED standard was formally released in May 2000; Version 2.1 was released in November 2002.[29]

US state or regional green building guidelines include:

- New York's High Performance Building Guidelines (1999).[30]
- Pennsylvania's Guidelines for Creating High Performance buildings (1999).[31]

"Building for Sustainability: Six Scenarios for the David and Lucille Packard Foundation Los Altos Project," October 2002. Available on-line at: http://www.packard.org/pdf/2002Report.pdf.
This comprehensive study evaluates the life cycle cost of six increasingly green designs, each built to a different standard of sustainability. Increases in initial capital costs are weighed against decreases in operating costs to determine net present value (NPV) for each building type over a 30, 60 and 100 year period. The study concludes, even without taking into account most externalities, that life cycle cost for a green building is considerably lower than for a conventional one.

In addition, there are a dozen or more local applications of LEED, generally adding more stringent requirements as part of state certification. Federal work on green buildings, coordinated by DOE's Federal Energy Management Program, has also developed important programs and resources on green building best practices. [32]

LEED as the US Green Building Standard

The United States Green Building Council (USGBC), a national non-profit entity, developed the Leadership in Energy and Environmental Design (LEED) Green Building Rating System™[33] to rate new and existing commercial, institutional, and high-rise residential buildings according to their environmental attributes and sustainable features. The LEED system utilizes a list of 34 potential performance based "credits" worth up to 69 points, as well as 7 prerequisite criteria, divided into six categories:

- Sustainable Sites
- Water Efficiency
- Energy and Atmosphere
- Materials and Resources
- Indoor Environmental Quality
- Innovation & Design Process

LEED allows the project team to choose the most effective and appropriate sustainable building measures for a given location and/or project. These "points" are then tallied to determine the appropriate level of LEED certification. See Appendix A for a full list of LEED Version 2.1 prerequisites and credits.

Four levels of LEED certification are possible; depending on the number of criteria met, and indicate increasingly sustainable building practices:

LEED Certified	26-32	points
LEED Silver	33-38	points
LEED Gold	39-51	points
LEED Platinum	52+	points

There is a general perception that LEED is becoming the standard for US green building design. As the industry magazine *Health Facilities Management* described in October 2002, "LEED has become the common benchmark for sustainability."[34] Although imperfect and still evolving, LEED has rapidly become the largest and most widely recognized green building design and certification program in the US, and probably in the world.

LEED was first introduced through a Pilot Program, and twelve buildings received version 1.0 certification in March 2000. Version 2.0 was released shortly thereafter for use as a design and certification tool. At the end of 2000, about 8 million square feet of buildings were undergoing

LEED certification. By early 2003, this number had jumped to over 100 million square feet. As of December 2002, of all new construction projects in the United States, an estimated 3% had applied for LEED certification, including 4% of schools, 16.5% of government buildings and 1.1% of commercial projects.[35] In addition, many buildings use LEED as a design tool without going through the certification process.[36] LEED's use and impact is therefore more pervasive than the figures suggest. All indications are that this explosive growth will continue. Despite its limitations, the strength and likely future durability of LEED and its definition of green buildings derives from several factors:

- LEED is broad and democratic in nature, currently with 3000 organizations representing all sectors of the building industry. Membership has roughly doubled annually over the last three years. [37]
- LEED continues to change through large, professional, voluntary committees, and a staff that is responsive to the evolving needs of its large and diverse membership. New products are being developed, including: LEED for Existing Buildings, LEED for Commercial Interiors, LEED for Core and Shell, LEED for Homes, LEED for Neighborhood Developments, and LEED for Multiple Buildings.[38]
- The USGBC spends millions of dollars each year to support LEED in a number of ways, including: an extensive training program; the LEED Accredited Professional exam; a Resource guide; LEED templates; an extensive LEED website for registered projects, technical data and scientific committees; and a growing staff of professionals dedicated to LEED.

States and municipalities can create local applications of LEED, generally adding more stringent regional requirements. This approach has been used in Portland, Oregon[39] and Seattle, Washington.[40] These programs require buildings to receive LEED certification, but are tailored to meet the specific resource concerns of the region.[41]

Many other jurisdictions are currently creating LEED-based guidelines and ordinances. Some have developed guidelines that closely follow LEED but are not viewed as LEED compatible,

such as the High Performance Guidelines of North Carolina's Triangle Region.[42] The USGBC's recent publication, *Making the Business Case for High Performance Green Buildings*, co-produced with the Urban Land Institute and The Real Estate Roundtable, provides a useful overview of green building benefits as well as a list of cities, states and other entities that have adopted LEED.[43]

LEED in California

There are more LEED registered projects within California – over 140 as of August 2003[44] – than in any other state. In 2001, in support of state greening efforts, California's Sustainable Building Task Force developed the LEED Supplement for California State Facilities.[45] This regionalized supplement to LEED V.2.0 is intended for guidance purposes and is not required for use in state projects. It provides information on California codes, policies and practices and is hosted on the CIWMB's website[46] for public use, though it has not been officially adopted.

On the local level, LEED has been adopted in a number of California municipalities. The city of San Jose,[47] San Francisco city and county,[48] the city of San Diego,[49] the city of Santa Monica,[50] San Mateo County,[51] and Los Angeles city and county[52] have all made commitments to LEED. The city of Oakland[53] and Alameda County[54] and have developed their own LEED-based green building guidelines. The city of Pleasanton recently passed an ordinance requiring both public and private buildings to meet the standards of LEED Certified level, subject to a few modifications.[55]
As an interim step towards the adoption of LEED at the state level, the California Sustainable Building Task Force, in collaboration with the Department of General Services, has developed

two lists of technologies that are intended to guide development of new buildings.[56] The Tier 1 list includes many green technologies – such as "cool roofs" (described in Section IX) – that have been predetermined as cost-effective by the Department of Finance and are expected to be included in new construction. The Tier 2 list includes technologies that should be included in new designs as long as they are cost justified, and as the project budget allows.

In reality Tier 1 and Tier 2 technologies are inconsistently included in construction. Part of the reason is that the benefits of green design are best achieved when green technologies and practices are adopted as part of an integrated design rather than on a piecemeal basis. An integrated green building design approach – such as LEED – provides a way to incorporate green technologies and practices in a way that is more likely to be cost-effective. [57]

In addition to LEED, another rating system has been developed specific to K-12 schools in California. The Collaborative for High Performance Schools, or CHPS, is a diverse group of government, utility, and non-profit organizations with a unifying mission to improve the quality of education for California's children.[58] The goal of the CHPS is to create a new generation of high performance school facilities in California. The focus is on public schools and levels K-12, although many of the design principals apply to private schools and higher education facilities as well. High performance schools are healthy, comfortable, resource efficient, safe, secure, adaptable, and easy to operate and maintain. They promote higher test scores, help school districts retain quality teachers and staff, reduce operating costs, increase average daily attendance (ADA), reduce liability, and promote environmental stewardship and joint use opportunities.

CHPS has developed a three volume Best Practices Manual for High Performance Schools, including a set of design criteria to "rate" CHPS schools.[59] Different from LEED, CHPS is self-certifying, and CHPS schools must score 28 out of 81 possible points for eligibility.

II. Important Assumptions

Life Cycle Assessment (LCA)

This report uses a life cycle costing (LCC) approach to evaluate and integrate the benefits and costs associated with sustainable buildings. Life cycle costing, often confused with the more rigorous life cycle assessment (LCA) analysis, looks at costs and benefits over the life of a particular product, technology or system. LCA, in contrast, involves accounting for all upstream and downstream costs of a particular activity, and integrating them through a consistent application of financial discounting. The result – if data is available -- is a current "cradle to grave" inventory, impact assessment and interpretation (e.g., a net present value estimate). However, the art and science of calculating true life cycle impacts and costs of green buildings is still evolving and is generally not practiced. Currently, decisions on whether or not to invest in a green building are typically based only on first costs plus, in some cases, a discounted value of lowered energy and water bills. This report seeks an approach that draws on the discipline of LCC practices to identify and clearly document the benefits and costs of the most important green building attributes, including some that are generally not explicitly considered in building investment decisions.

There are a number of international green building assessment programs that provide tools for evaluating building performance across a large range of green performance criteria.[60] European LCA work is extensive and some of it ties into the internationally accepted ISO quality certification process.[61] A popular Canadian core and shell assessment tool – Athena [62] – was recently used in designing the Clearview Elementary School in Pennsylvania[63] and the Battery Park City residential construction project in New York City.[64] BEES, a building materials selection tool developed by the U.S. Government's National Institute of Standards and Technology (NIST), is useful for specifying materials and can be used with Athena to create a whole building life cycle analysis.[65] Some of the most rigorous science-based LCA tools are not available in English – these include LEGOE from Germany, an LCA program that runs in the background with CAD software,[66] and EcoQuantum from Holland.[67]

Altogether, there are a dozen or more life cycle tools each with various strengths and limitations – Athena, for example, despite its strengths, is currently based only on Canadian data.[68]

For a good overview of international life cycle development, see: "Evolution and Development of the Conceptual Framework and Methodology of Life-

This report does not use any of these specific tools. Rather, it follows the general life cycle approach in evaluating a broad spectrum of costs and benefits using the limited data available. There are many substantial information gaps preventing a full life cycle cost assessment of green buildings. To cite just two examples: data on the full cost of water is incomplete, and available data on emissions from energy use should (but generally does not) reflect the life cycle emissions from energy extraction, transportation, use and disposal, as well as from energy generation. The objective of this report is to aggregate the available data about green buildings, and to develop a reasonable net present value estimate of their future associated costs and benefits.

Use of Present Value (PV) and Net Present Value (NPV)

The overarching purpose of this report is to answer the following question: Does it make financial and economic sense to build a green building? Green buildings may cost more to build than conventional buildings, especially when incorporating more advanced technologies and higher levels of LEED, or sustainability. However, they also offer significant cost savings over time.

This report will seek to calculate the current value of green buildings and components on a present value (PV) or net present value (NPV) basis. PV is the present value of a future stream of financial benefits. NPV reflects a stream of current and future benefits and costs, and results in a value in today's dollars that represents the present value of an investment's future financial benefits minus any initial investment. If positive, the investment should be made (unless an even better investment exists), otherwise it should not.[69] This report assumes a suitable discount rate over an appropriate term to derive an informed rationale for making sustainable building funding decisions. Typically, financial benefits for individual elements are calculated on a present value basis and then combined in the conclusion with net costs to arrive at a net present value estimate.

Net present value can be calculated using Microsoft's standard Excel formula:

$$NPV = \sum_{i=1}^{n} \frac{values_i}{(1+rate)^i}$$

The formula requires the following:

- **Rate**: Interest Rate per time period (5% real)
- **Nper (n)**: The number of time periods (20 years)
- **Pmt (values):** The constant sized payment made each time period (annual financial benefit)

This provides a calculation of the value in today's dollars for the stream of 20 years of financial benefits discounted by the 5% real interest rate. It is possible to calculate the net present value of the entire investment - both initial green cost premium and the stream of future discounted financial benefits - by subtracting the former from the latter.

Cycle Assessment," *SETAC Press*, January 1998. Available as an addendum to *Life-Cycle Impact Assessment: The State-of-the-Art*. See: http://www.setac.org. [69] See: http://www.investorwords.com/cgi-bin/getword.cgi?3257.

Discount Rate
To arrive at present value and net present value estimates, projected future costs and benefits must be discounted to give a fair value in today's dollars. The discount rate used in this report is 5% real. This rate is stipulated for use by the California Energy Commission[70] and is somewhat higher than the rate at which the state of California borrows money through bond issuance.[71] It is also representative of discount rates used by other public sector entities.[72]

Term
California's Executive Order D-16-00, committing California to provide energy efficiency and environmental leadership in its building design and operation, stipulates that "a building's energy, water, and waste disposal costs are computed over a twenty-five year period, or for the life of the building."[73] Buildings typically operate for over 25 years. A recent report for the Packard Foundation shows building life increasing with increasing levels of greenness. According to the Packard study, a conventional building is expected to last 40 years, a LEED Silver level building for 60 years and Gold or Platinum level buildings even longer.[74] In buildings, different energy systems and technologies last for different lengths of time – some energy equipment is upgraded every 8 to 15 years while some building energy systems may last the life of a building. This analysis conservatively assumes that the benefits of more efficient/sustainable energy, water, and waste components in green buildings will last 20 years, or roughly the average between envelope and equipment expected life.

Inflation

This report assumes an inflation rate of 2% per year, in line with most conventional inflation projections.[75] Unless otherwise indicated, this report makes a conventional assumption that costs (including energy and labor) as well as benefits rise at the rate of inflation – and so present value calculations are made on the basis of a conservative real 5% discount rate absent any inflation effects. In reality, this is quite an oversimplification and a more detailed analysis might attempt to make more accurate but complicated predictions of future costs. In particular, energy costs are relatively volatile, although electricity prices are less volatile than primary fuels, especially gas.

LEED as a Basis

Although this report will look at the lessons offered from a range of green design programs, LEED is used as the common basis for comparison because it has become the dominant definition of green buildings in the United States. For example, in seeking to quantify a building's "greenness," it will be described by its LEED level or equivalent (e.g., LEED Silver, representing 33 to 38 points).

A Note about Data Sources

The last few years have seen the emergence of meta-studies that screen, select, and provide up-to-date and well-linked compilations of important data sets related to green building benefits. For example, the Carnegie Mellon BIDS program has screened over one thousand studies to come up with approximately 90 of the most rigorous studies on the productivity impacts from green and high performance building designs.[76] Similarly, the US Green Building Council keeps a regularly updated list of all the cities and municipalities that use LEED or some version of LEED. Some areas, notably water and waste, lack comprehensive on-line databases. A brief annotated review of sources is included as an appendix for these two sections (Appendix L).

In many cases there is no recent reliable California data. For example, there appears to be no California-specific study on the environmental benefits of waste reduction. Similarly, in the last decade there have been no publicly available, comprehensive studies on California that calculate the full benefits (such as avoided transmission and distribution costs) of reduced energy demand, e.g., from measures such as on-site generation and energy efficiency. These gaps are noted in the text and are reflected in recommendations at the end of the report for additional research.

III. The Cost of Building Green

The Problems of Determining Cost

There has been a widespread perception in the real-estate industry that building green is significantly more expensive than traditional methods of development. A half dozen California developers interviewed in 2001 estimated that green buildings cost 10% to 15% more than conventional buildings.[77] The Sustainable Building Task Force *Blueprint*[78] identifies several obstacles to sustainable buildings, including:

- Incomplete integration within and between projects.
- Lack of life cycle costing.
- Insufficient technical information.

The *Blueprint* notes that because of these barriers, "many sustainable building applications are prematurely labeled as 'unproven' or 'too costly.'" [79] *Consulting – Specifying Engineer* echoed this view in its October 2002 issue, indicating that: "the perception that green design is more expensive is pervasive among developers and will take time to overcome" and "inhibiting green design is the perception that 'green' costs more and does not have an economically attractive payback." [80]

There is a growing body of performance documentation and online resources related to green building. For example, a new online source developed through a partnership of the US Department of Energy, Environmental Building News, the US Green Building Council, Rocky Mountain Institute, and the AIA Committee on the Environment includes 42 green building case studies, 13 of which are located in California.[81] Despite these advances, there is still little published data about actual cost premiums for green buildings. This information gap is compounded by the fact that the USGBC does not require that cost information be included with submissions for LEED certification.

Many developers keep cost information proprietary. In addition, even if developers are willing to share their cost data, determining a precise "green premium" for a given project is often very difficult for several reasons:

- Developers typically only issue specifications and costs for the designed building, not for other green options. Individual green items are sometimes priced out in comparison to non-green ones, but this is not the norm and does not provide a basis for cost comparison between green and conventional whole building design.

- Some green buildings being built today are showcase projects that may include additional and sometimes costly "finish" upgrades that are unrelated to greenness but that nonetheless are counted toward the green building cost increase.
- The design and construction process for the first green building of a client or design/architectural firm is often characterized by significant learning curve costs, and design schedule problems such as late and costly change orders.
- The relative newness of green technologies and systems can make designers, architects and clients conservative when using them. They may oversize green building systems and not fully integrate them into the building, thereby reducing cost savings and other benefits. Similarly, cost estimators may add uncertainty factors for new green technologies they are not familiar with, and these can compound, further inflating cost estimates.

National Green Building Leaders

Although more members and registered projects are located in California than in any other state, Pennsylvania, Massachusetts, Washington and Oregon have the most extensive, documented experience with green building and LEED.[82] Therefore, despite the general deficiency of published data on the cost of building green, there is substantial recent evidence from these and other entities to indicate that building green is less expensive than many developers think. In particular, this data comes in part from two municipalities with extensive experience building LEED projects: Pennsylvania and Seattle, WA.

Pennsylvania

Over the past several years, the state of Pennsylvania has constructed five LEED registered projects (three will be completed in 2003). Pennsylvania's green building experience now enables it to build LEED Silver buildings that cost virtually the same as traditional buildings.[83] The state's first LEED Gold level green building, a 40,000 square foot office building in Cambria, PA, was built at $90 per square foot, just under comparable market rates for conventional buildings (See Appendix C).[84] Much of Pennsylvania's success comes from the state's ability to negotiate better prices from green manufacturers. Most green materials used in this project cost the same or less than the traditional alternative, reinforcing the fact that green design has matured and broadened into the mainstream and is no longer a cutting edge trend.[85]

Seattle, WA

Seattle was the first municipality in the nation to adopt a LEED Silver requirement for larger (over 5000 ft^2 occupied space) construction projects. The city currently has 11 LEED registered projects.

[82] Pennsylvania, Oregon and Washington have more projects per capita, per Gross State Product, and per Construction Gross State Product than California or other states across the country. See Appendix B for a Graphical Representation.

Detailed cost data from these projects has not yet been released, but according to a draft report, LEED Silver certification should not add cost to a project provided the following: [86]

- LEED Silver is made a requirement in the Request for Qualification for the Design Team and embedded within the construction documents, building construction, and commissioning.
- The selected Design Team has sustainable design embedded within the firm's design culture.
- Contractors, Property Managers, Real Estate Analysts, Budget Analysts, Crew Chiefs and Custodians are included on the Design Team.
- Selected sustainable design strategies are "whole system" in nature and integrated design solutions are pursued that cannot be peeled off from the base project as "add alternates."

A Cost Analysis of 33 LEED Projects

Cost data was gathered on 33 individual LEED registered projects (25 office buildings and 8 school buildings) with actual or projected dates of completion between 1995 and 2004. These 33 projects were chosen because relatively solid cost data for both actual green design and conventional design was available for the same building.

Virtually no data has been collected on conventional buildings to determine what the building would cost as a green building. And, surprisingly, most green buildings do not have data on what the building would have cost as a conventional building. To be useful for this analysis, cost data must include both green building and conventional design costs for the same building. Typically this data is based on modeling and detailed cost estimates. (As indicated elsewhere, LEED does not currently require that cost data for both conventional and green design be submitted. This report recommends that the USGBC consider making this a prerequisite or offer part of a credit for providing this data).

Attempts to compare the cost of a specific green building – such as a school – with other buildings of similar size and function in a different locality provide little help in understanding the cost of green design. The added cost impact of designing green may be very small compared with other building costs such as the cost of land and infrastructure. Therefore, a meaningful assessment of the cost of building green requires a comparison of conventional and green designs for the same building only.

Consequently, there is very little solid data on the additional costs associated with green design. Information for this report was collected primarily through a broad literature review; from several dozen interviews with architects and other senior building personnel; written and verbal communications with California's Sustainable Building Task Force members, USGBC staff, attendees at the Austin green building conference, and members of the Green Building Valuation Advisory Group; through a query posted in the Environmental Building News; and from others.

---

[86] Lucia Athens and Gale Fulton, "Developing a Public Portfolio of LEED™ Projects: The City of Seattle Experience." Electronic copy received from authors on December 20, 2002. Available at: http://www.usgbc.org/expo2002/schedule/documents/DS509_Athens_P126.pdf.

A resulting table containing each project name, location, building type, date of completion, green premium and certification level or equivalent can be found in Appendix C. Note that many of these buildings have not yet been certified by the USGBC. In these cases, the LEED level indicated is an assessment by the architect and/or client team reflecting very detailed analysis and modeling – this is viewed as a relatively accurate prediction of final LEED certification level.

While the size of the data set is not large, analysis provides meaningful insights into the cost premium for green buildings. Figures III-1 and III-2 show that, on average, the premium for green buildings is about 2%. The eight rated Bronze level buildings had an average cost premium of less than 1%. Eighteen Silver-level buildings averaged a 2.1% cost premium. The six Gold buildings had an average premium of 1.8%, and the one Platinum building was at 6.5%. The average reported cost premium for all 33 buildings is somewhat less than 2%.[87]

Figure III-1. Level of Green Standard and Average Green Cost Premium

Level of Green Standard	Average Green Cost Premium
Level 1 – Certified	0.66%
Level 2 – Silver	2.11%
Level 3 – Gold	1.82%
Level 4 – Platinum	6.50%
Average of 33 Buildings	1.84%

Source: USGBC, Capital E Analysis

[87] See Appendix C for a complete list of the 33 projects, their LEED levels, and green premiums.

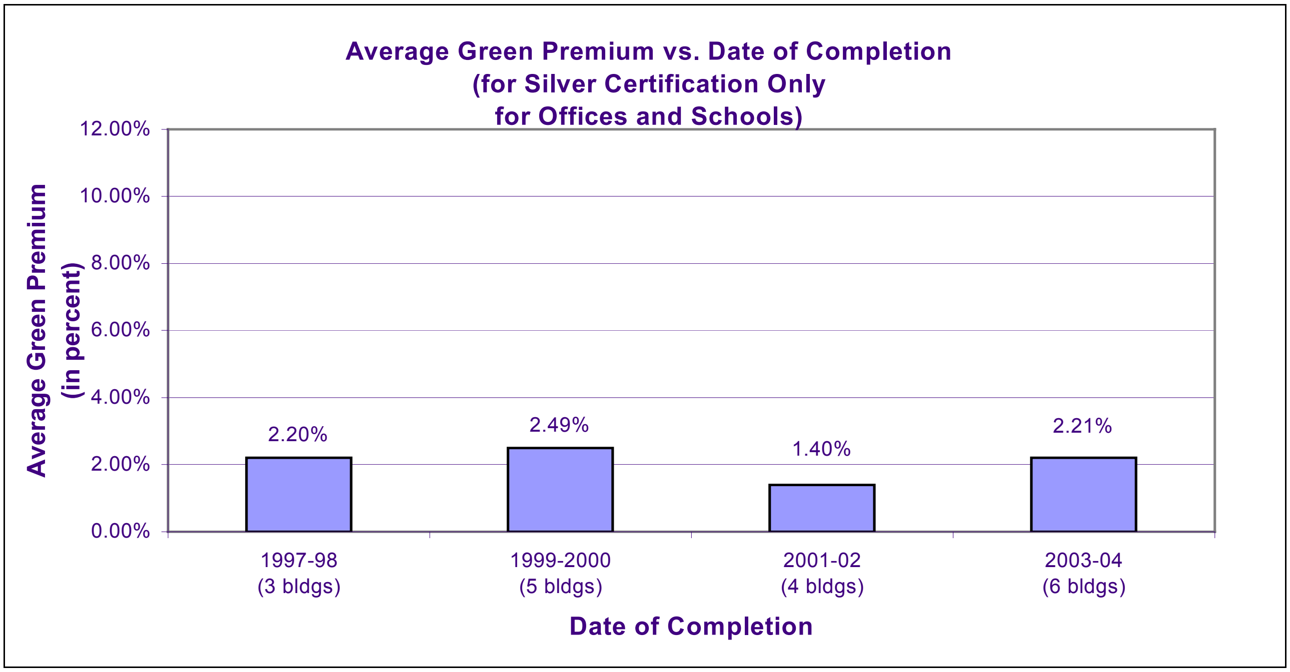
Figure III-3. Year of Completion and Average Green Cost Premiums for Buildings with Silver Certification

Year of Completion	Average Green Cost Premium
1997-1998	2.20%
1999-2000	2.49%
2001-2002	1.40%
2003-2004	2.21%
Avg. of 18 Silver buildings	2.11%

Figure III-4. Average Green Cost Premium vs. Date of Completion for Buildings with Silver Certification



Source: USGBC, Capital E Analysis

There is evidence that building green gets less expensive over time, with experience. However, an expected downward cost trend of the green cost premium is not clear in this data. The green premium is lowest for the most recently completed buildings (2001-02) and higher for buildings projected to be completed in 2003 and 2004. This data reflects two things. First, 2003-2004 buildings costs are projections and these tend to be slightly high (conservative). It can be expected that as these buildings are completed, the actual cost premium will, on average, be lower than projected in this data. Second and perhaps more importantly, the reported data includes both first time green buildings and buildings that may be the third or fourth green building by the same owner/designer builder team. Thus the data includes both relatively higher cost first timers and the efforts of experienced teams that generally achieve lower cost premiums.

The trend of declining costs associated with increased experience in green building construction has been experienced in Pennsylvania,[88] as well as in Portland and Seattle. Portland's three reported completed LEED Silver buildings (see Appendix C) were finished in 1995, 1997, and

[88] Data provided by John Boecker, L. Robert Kimball and Associates, A/E Firm for the Pennsylvania Department of the Environment Cambria Office Building, Ebensburg, PA, the PA Department of Environmental Protection Southeast Regional Office. Norristown, PA, and the Clearview Elementary School, York, PA.
See: http://www.lrkimball.com/Architecture%20and%20Engineering/ae_experience_green.htm.

2000. They incurred cost premiums of 2%, 1% and 0% respectively.[89] Seattle has seen the cost of LEED Silver buildings drop from 3-4% several years ago to 1-2% today.[90]

A second data anomaly is that reported cost levels for LEED Gold buildings are slightly lower than for Silver buildings, whereas the higher performance level requirements to achieve Gold would be expected to cost more than Silver levels. In part, this anomaly reflects the small data set – the Gold premium is an average across only six buildings. As additional green building data is assembled, costs are likely to more closely follow the rising cost levels associated with more rigorous levels of LEED. Nonetheless, the data indicates that it is possible to build Gold level buildings for little additional cost. The higher performance levels associated with Gold buildings (described below in Health and Productivity and other sections), combined with their potentially low cost premiums – as indicated in this small data set – suggest that, based on available data, LEED Gold may be the most cost effective design objective for green buildings.

Implications for California

The conclusions above indicate that while green buildings generally cost more than conventional buildings, the "green premium" is lower than is commonly perceived. As expected, the cost of green buildings generally rises as the level of greenness increases, while the premium to build green is coming down over time. Importantly, the cost of green buildings tends to decline with experience in design and development, as clients and their design and architecture teams move beyond their first green building. This trend suggests that California develop policies and procedures to favor the hiring of more experienced green building teams, and that this experience be embedded throughout the design team. Additionally, development of multiple green buildings within a particular California state agency or university can be expected to result in declining costs per building to that organization.

Assuming conservative, relatively high California commercial construction costs of $150/ft^2 to 250/ft^2$,[91] a 2% green building premium is equivalent to $3-5/ft^2$. Use of lower construction costs in these calculations would tend to increase the reported cost effectiveness of green construction.

The rest of this report will attempt to quantify the size of financial benefits as compared with the costs of building green buildings.

---

[89] Data provided by Heinz Rudolf, BOORA Architects. See Portfolio/Schools at: http://www.boora.com/

[90] Lucia Athens, Seattle Green Building Program, Nov. 2002. See: http://www.cityofseattle.net/light/conserve/sustainability/.
The city is expected to soon release a review of over a dozen green Seattle buildings and specific costs premiums for these buildings.

[91] This is a reasonable, somewhat high (e.g. conservative) estimate as confirmed by Oppenheim Lewis Inc. and Anthony Bernheim, Principal, SMWM. Includes hard and soft costs (including design fees) associated with construction, but not land acquisition.

IV. Energy Use

Energy is a substantial and widely recognized cost of building operations that can be reduced through energy efficiency and related measures that are part of green building design. Therefore, the value of lower energy bills in green buildings can be significant. The average annual cost of energy in state buildings is approximately $1.47/ft^2.[92] On average, green buildings use 30% less energy than conventional buildings[93] – a reduction, for a 100,000 ft^2 state office building, worth $44,000 per year, with the 20-year present value of expected energy savings worth over half a million dollars.[94]

A detailed review of 60 LEED rated buildings, including 5 LEED rated buildings in California, clearly demonstrates that green buildings, when compared to conventional buildings, are:

- On average 25-30% more energy efficient (compared with ASHRAE 90.1-1999 and, for California buildings, Title 24 baselines);[95]
- Characterized by even lower electricity peak consumption;
- More likely to generate renewable energy on-site; and
- More likely to purchase grid power generated from renewable energy sources (green power and/or tradable renewable certificates.

Although the environmental and health costs associated with air pollution caused by non-renewable electric power generation and on-site fossil fuel use are generally externalized (not considered) when making investment decisions, the energy reductions realized through the design and construction of green buildings reduce pollution and lower the environmental impact of conventional power generation.[96] This report seeks to quantify some of the benefits, including the value of peak power reduction (in this section) and the value of emissions reductions (in Section V) associated with the energy strategies integrated into green building design.

---

[92] Over 95% of primary energy use in California state buildings is electricity, with the balance natural gas. Data provided by California Department of General Services, Real Estate Services Division, Building Property Management Brach. "Energy Cost Estimates," December 2002. See also *Appendix I*. 2002 energy costs were estimated at $1.60/ft^2/yr, but average California electricity rates are conservatively projected to drop from $0.12/kWh to $0.11/kWh. Energy use and cost data come directly from utility bills.

[93] Note: As a result of the energy crisis in California and various Flex-Your-Power energy efficiency campaigns, the State has already reduced electricity use in most buildings by close to 20%. Absolute energy savings typical of green buildings will be lower for energy efficient state buildings, which have already realized much of the benefit associated with energy efficiency. However the percentage reduction in energy use in these buildings is comparable to less efficient buildings – see subsequent data and discussion.

[94] Using 5% real discount rate over 20 year term, as discussed above. While both improved energy efficiency and on site generation result in lower energy bills, the reduced energy costs only capture a portion of the benefits accrued to the state. See for example: CEC Environmental Performance Report, http://www.energy.ca.gov/reports/2001-11-20_700-01-001.PDF.

[95] Based on analysis of Energy and Atmosphere Credit 1 – Energy Optimization points awarded to all LEED-NC v2 Certified projects.

[96] See: Lovins et al., "Small is Profitable," RMI, 2002. Available at: http://www.rmi.org.

Data on green buildings is somewhat limited because of the relative youth of a quantifiable definition of 'green' (this report uses the U.S. Green Building Council's LEED Green Building Rating System), a limited data set (60 LEED rated Buildings), incomplete reporting and/or insufficient reporting requirements (of the 60 LEED rated buildings, 19 were Certified under the LEED v1.0 Pilot which had different reporting requirements), and client preference for non-disclosure of data. All these limitations are evident in the small data set of five LEED rated buildings in California, including:

- Toyota Motor Sales South Campus Office Development, Torrance – LEED v2.0 Gold, 630,000 ft^2, completed in 2002.
- Ford Motor Company Premier Automotive Group North American HQ, Irvine – LEED v2.0 Certified, 253,000 ft^2, completed in 2001.
- William and Flora Hewlett Foundation Headquarters, Menlo Park - LEED v2.0 Gold, 48,000 ft^2, completed in 2002.
- Capital Area East End Complex 225, Sacramento – LEED v2.0 Gold, 479,000 ft^2, completed in 2003.
- UCSB Donald Bren School of Environmental Science and Management, Santa Barbara – LEED v1.0 Platinum, 90,000 ft^2, completed in 2002.

Data on energy use in these buildings was obtained directly from the USGBC,[97] and included a detailed review of the Energy Cost Budget documents required for award of LEED energy performance. Because some project teams have requested that their project data be kept confidential the data is presented in a format that ensures that the performance characteristics of specific buildings are masked. These California LEED rated buildings on average demonstrate energy efficiency commensurate with the 25-30% national average reduction for green buildings.[98] Energy efficiency (relative to a California Title 24 baseline) improvements for the five buildings (in order of lowest to highest) are 22%, 30%, 30%, 35%, 40%.

The Price of Energy

Calculating the current financial value of lower future energy consumption requires estimating future energy costs, and this is complicated by the rapidly changing tariff structures of California's utilities. California electricity rates have climbed steeply over the past several years, in large part due to surcharges mandated by the CPUC in response to the recent electricity crisis. As indicated in Figure IV-1, peak electricity prices are as high as $0.34 per kWh for buildings (including most state buildings) that are on time-of-use rates. At this time, it is not clear what future electricity prices will be.[99]

---

[97] Data provided by the US Green Building Council, December 2002 (Brendan Owens, LEED Engineer).

[98] Because the energy performance baseline in California is Title 24, which is more rigorous than the prevailing national ASHRAE standard, it might be expected that energy reduction in California green buildings would be less than for LEED buildings nationally. This does not appear to be the case. Several reasons for this may include relatively high California energy prices (and recent price increases) that would tend to increase incentives for aggressive energy reduction measures, and the existence of California standards in areas other than energy – such as recycling and indoor environmental quality - that provide a higher baseline for non-energy performance for California sustainable buildings, and that may make energy improvements below the Title 24 baseline not more costly *relative* to other dimensions of green design.

[99] McAuliffe, Pat. California Energy Commission, Office of Commissioner Art Rosenfeld, December 2002.

The majority of California state buildings are on tariffs with time-of-use rates. These include relatively high electricity prices during periods of peak grid-wide electricity use, in an attempt to reduce peak consumption. The Pacific Gas & Electric (PG&E) commercial tariff, in Figure IV-1 below, is typical of these time-of-use commercial rates.

Figure IV-1. PG&E A-6 Time of Use Rate Schedule (simplified)

Customer Charge	**Season**	**Time-of-Use Period**	**Energy Charge** (per kWh)	**1/4/01 Energy Surcharge** (per kWh)	**6/1/01 Energy Surcharge** (per kWh)	**Total Energy Charge** (per kWh)	**"Average" Total Rate** (per kWh)
Single phase service per meter/day =$0.26612; Polyphase service per meter/day =$0.39425. Plus Meter charge =$0.22341 per day for A6 or A6X; =$0.06571 per day for A6W	**Summer**	On peak	$0.23258	$0.01000	$0.10064	**$0.34322**	$0.14487
		Part Peak	$0.10288	$0.01000	$0.04551	**$0.15839**	
		Off Peak	$0.05618	$0.01000	$0.03551	**$0.10169**	
	Winter	Part Peak	$0.11562	$0.01000	$0.04551	**$0.17113**	
		Off Peak	$0.07169	$0.01000	$0.03551	**$0.11720**	

Source: http://www.pge.com/tariffs/CommercialCurrent.xls

PG&E's average commercial rate is currently about $0.15 per kWh.[100] San Diego Gas & Electric (SDG&E)[101] and Southern California Edison (SCE)[102] have similar rates. Other utilities, such as Sacramento Municipal Utility District (SMUD) have slightly lower average commercial rates. The current average cost of electricity for state buildings is about $0.12/kWh, reflecting a concentration of state buildings in lower tariff utility districts, such as SMUD.[103] This rate is likely to drop by the end of 2003 as a substantial temporary surcharge (intended to help California utilities regain solvency) is dropped. However, there may be an additional bond surcharge of about $0.005/kWh imposed in 2003. In addition, the CPUC may implement a $0.50+/kWh "super peak" surcharge on the peak hours of 15 of the hottest (and highest peak electricity use) days in the year.[104] The CEC believes that at end of 2003 rates may drop to about $0.11/kWh,

[100] For PG&E rates, see: http://www.pge.com/tariffs/CommercialCurrent.xls and http://www.pge.com/tariffs/GNR2_Current.xls.

[102] For SCE Rates, see: http://www.sce.com/NR/sc3/tm2/pdf/ce87-12.pdf and http://www.sce.com/sc3/005_regul_info/005a_tariff_book/005a3_rates/005a3b_biz_rates.htm.
[103] Data provided by the California Energy Commission, Office of the Supervisor of Rates, December 2002. See also: Electricity in California. California Energy Commission. Available at: http://www.energy.ca.gov/electricity/index.html#rates.
[104] California Energy Commission. Office of Energy Commissioner Art Rosenfeld. November 2002.

and that this is a good, conservative estimate for future average commercial electricity prices (Note: Higher electricity rates would increase the benefits of green buildings).[105]

This report therefore assumes a real average commercial electricity price for 2003 and beyond of $0.11/kWh. This rate is used for calculations involving schools as well, even though schools are more evenly distributed through higher tariff utility districts (benefits accruing to green schools may therefore be understated in this analysis). Projected future electricity savings are discounted at the 5% (real) rate. However, calculating the full benefits of lower energy costs from green buildings is more complex than this because green buildings tend to use disproportionately less energy during peak times, when electricity is more valuable and expensive.

Cutting Peak Power

The unique integrated design and construction process that green buildings typically follow considers the building holistically. Interactions between competing building systems (lighting vs. cooling, fresh air vs. humidity control, etc.) are therefore analyzed simultaneously, allowing the building designers to reduce peak power demand by downsizing building systems, particularly air conditioning and lighting loads, while providing a comfortable indoor environment. For most of California (except the generally foggy northern coast) and much of the US (especially in the South and Midwest) air conditioning is the dominant energy user during peak load. The largest and third largest electricity demands, respectively, in California during a typical 50,000 MW peak load period are commercial air conditioning – representing 15% of peak load, and commercial lighting – representing 11% of peak load.[106] By encouraging integrated design and awarding credit for optimization of building energy systems, LEED provides strong incentives to cut both of these peak demand uses.

LEED encourages:

- *Integrated design*: Project teams consider building systems in total to optimize competing demands.
- *High Performance Lighting*: Incorporation of more efficient lights, task lighting, use of sensors to cut unnecessary lighting, use of daylight harvesting and other advanced lighting techniques and technologies. These measures can significantly reduce power demand from electric lights. In hot weather, this reduction has the added advantage of reducing cooling loads in a building, which in-turn reduces required air conditioning.
- *Increased Ventilation Effectiveness*: Helps cut air conditioning load during peak through improved system optimization.
- *Underfloor Air Distribution Systems*: Use of a plenum below a raised floor to deliver space conditioning. Typically cuts fan and cooling loads, substantially lowering air conditioning load (see "Underfloor Air" in Section IX).

---

[105] Data provided by the California Energy Commission, Office of the Supervisor of Rates, December 2002. See also: California Energy Commission. "2002-2012 Electricity Outlook Report." February 2002. Available at: http://www.energy.ca.gov/reports/2002-02-14_700-01-004F.PDF.

[106] John Wilson, Art Rosenfeld and Mike Jaske, "Using Demand Responsive Loads to Meet California's Reliability Needs," paper presented at 2002 ACEEE summer conference. Available from: jwilson@energy.state.ca.us. Note: the number two user of electricity in California is residential air conditioning.

- *Commissioning*: A systematic process to ensure that building systems are designed, installed and operating as planned. Incorporation of commissioning tends to increase building system performance and cut energy use, helping to ensure that design objectives and performance targets are met and that energy savings persist (see "Commissioning" in Section IX).
- *Heat Island Reduction Measures*: By increasing the reflectivity of roofs and other typically dark surfaces, it is possible to lower building and urban temperatures, in turn reducing air conditioning loads and peak demand (see "Cool Roofs" in Section IX).
- *On-site Generation*: Two of the eight LEED Gold level buildings reviewed use photovoltaics (PV) to generate 20% of their power on site. PV is coincident with peak power usage, and so contributes to peak demand reduction.

Although peak demand reduction data is not provided or is incomplete for some buildings (LEED certification requirements do not currently require peak reduction information), California LEED rated buildings, like non-California buildings, generally show larger reductions in peak demand than in overall energy use. For the three California LEED rated buildings for which peak reduction data was submitted, electricity for space cooling and lighting (of conditioned space) varied widely but indicated an average electricity peak demand reduction of 17%. This average includes a shift from electricity to natural gas for most space cooling in one of the buildings. The fuel switch from electricity to natural gas artificially inflates the electricity peak demand reduction in this building. A fourth California LEED building, for which incomplete data was submitted, indicates a 13% reduction in total building energy use by implementing natural ventilation strategies rather than relying solely on mechanical HVAC.

The very limited California data set indicates that peak demand reduction in California green buildings is significant and consistent with a preliminary estimate of 10% peak demand reduction below average energy reduction in green buildings. The correlation between peak demand reduction in green buildings evident in the limited data set warrants further research. Preliminary discussions, between report authors and the USGBC, are underway to modify LEED credit requirements to require peak demand reduction data in LEED documentation.

It is important to emphasize that there is not yet sufficient data to exactly predict peak demand reduction from green buildings. Uncertainties result from a limited data set, inconsistencies in documentation, incomplete documentation, technical issues such as fuel switching, and the large variability between building designs. Nonetheless the available green building data is significant and collectively indicates that green buildings - including green buildings in California - on average provide peak demand reduction that is significantly larger than average energy reduction.

LEED places a high priority on building energy performance. Energy efficiency (including building commissioning, renewable energy and green power) is the single largest LEED credit category and represents 27% of the total points available in the LEED Green Building Rating System. LEED rated buildings, on average, use 30% less energy than those that meet the standard energy requirements of Title 24 (for California buildings) or ASHRAE 90.1 (in the rest of the country). Additional confirmation comes from analysis of USGBC data for 21 LEED rated buildings (including 6 buildings in California) - 8 Certified buildings, 5 Silver buildings and 8 Gold buildings. Both analyses (looking at a partially overlapping set of buildings) indicate that Gold buildings are generally the most energy efficient and Certified buildings the least efficient.[107] On a weighted average basis, green buildings are 28% more efficient than conventional buildings and generate 2% of their power on-site from photovoltaics (the large

[107] This building data is from USGBC from buildings that have completed the LEED certification process.

majority of green buildings do not have on-site generation and the 2% on site generation average reflects significant on-site generation from a few green buildings).

Figure IV-2. Reduced Energy Use in Green Buildings as Compared with Conventional Buildings

	Certified	Silver	Gold	Average
Energy Efficiency (above standard code)	18%	30%	37%	28%
On-Site Renewable Energy	0%	0%	4%	2%
Green Power	10%	0%	7%	6%
Total	**28%**	**30%**	**48%**	**36%**

S*ource: USGBC, Capital E Analysis*

As discussed above, green buildings use an average of 30% less purchased energy than conventional buildings. In addition, green buildings are more likely to purchase "green power" for electricity generated from renewable energy sources. Green power purchases can take two forms:

- Customers can purchase green power directly from their utility or from a local green power provider. In this case customers are paying for electricity generated from renewable energy sources, typically by a local provider in the state or utility jurisdiction. About 40% of US electricity customers have this option.
- Customers can purchase green certificates, or green tags. In purchasing green certificates, a customer is buying ownership of the reduced emissions (and by implication the environmental and health benefits) associated with renewable power, even though the green generating facility is frequently not in the customer's vicinity. All electricity consumers have this option.

For 21 green buildings on which USGBC has collected data, 6% of the electricity purchased was green.[108] Two factors need to be considered in determining the net impact that green power purchases by green buildings have on emissions (discussed in Section V). First, a small and growing portion – slightly less than 1/2% of the general population – already buys green power.[109] This suggests that adoption of LEED provides a 5.5% net increase in green power purchases compared with conventional buildings. Secondly, LEED recently modified its green power purchase requirement to allow purchase of green certificates. With this change, 100% of LEED buildings now have the ability to get LEED credit for buying green power, providing virtually universal availability. This is in contrast to direct green power purchases, which are currently available in areas containing only 40% of the population. This broadening of the green power credit will therefore significantly increase the portion of LEED buildings that buy green power (an issue that should be explored in more detail).

[108] Data provided by the USGBC. Capital E analysis with USGBC, November and December 2002.
[109] Jan Hamrin. Center for Resource Solutions, communication January 12, 2003. This number includes business as well as residential consumers.

Because all buildings are now able to buy green power, in the form of certificates, this report assumes that the portion of green power purchased by LEED green buildings will rise from 6% to 9% - an increase proportionally less than the doubling in buildings that can buy green power and receive LEED credit for it. A conservative estimate is that the future difference between average green building green power purchase and total average building green power purchase will rise from 5.5% (cited above) to 8.5%. Note that this is equal to 6% of total electricity use in an average non-green building.

This report therefore assumes that an average green building in the near future will purchase 9% of its electricity from green sources, or about 8.5% more than an average conventional building. Since a green building uses only 70% of the electricity that a conventional building does, the emissions reduction value of green power purchases by a green building is effectively reduced to about 6%.

As indicated in figure IV-2, above, average green building use of conventional energy (and the resulting associated emissions) is therefore on average about 36% lower than conventional buildings.

Evaluation of LEED certification documentation for over a dozen buildings,[110] including four California buildings, indicates an approximate average reduction in energy use of 30%, but an average peak reduction of about 40%.[111] While the data set is limited, it nonetheless indicates that green buildings reduce peak demand to a greater degree than total energy consumption: green buildings have proportionately larger reductions in peak demand.

Energy Star, administered by the US EPA and DOE, is the best known national energy performance rating program. It recognizes buildings for superior energy performance – defined as the 25% most energy efficient portion of the market – based on actual energy usage. Unfortunately, like LEED, the Energy Star program does not evaluate peak demand reduction.[112] Both USGBC/LEED and EPA/Energy Star should gather and publish data on the peak demand reduction of, respectively, green and energy efficient buildings.

Value of Peak Power

Utility transmission and distribution (T&D) systems generally run at less than 50% capacity.[113] However, during periods of peak electricity use, the generation and T&D systems may be close to overloaded. The benefits of reduced consumption are largest during periods of peak power consumption – avoided congestion costs, reduced power quality and reliability problems, reduced pollution, and additional capital investment to expand generation and T&D infrastructure. The value of peak reduction is not just in avoided purchase of electricity, but also in avoided capacity

---

[110] Data provided by the USGBC, analysis by Capital E with USGBC. November and December, 2002

[111] Because USGBC does not require that peak load reduction data be submitted, the data quality is mixed and includes some buildings that specify peak load demand reduction and some building data that indicates this indirectly (e.g., through large reductions in air conditioning load). Additional building information reviewed provided no useful data on peak demand reductions.

[112] US EPA. Energy Star Technical Description for the Office Model. 2001.
Available at: http://www.energystar.gov/ia/business/evaluate_performance/technicaldescription.pdf.

[113] Electricity generation and distribution assets are less than half utilized most of the time. See: Amory Lovins et al, "Small is Profitable," RMI, 2002. http://www.smallisprofitable.org/.

and T&D costs.[114] Thus, energy benefits of green buildings need to be quantified not solely based on reduced energy use but also on reduced peak electricity demand.

Approaches for determining the value of peak demand reduction include: 1) marginal cost as imposed in time-of-use rates, and 2) the actual marginal cost of peak power – the cost of building peaking power plants, T&D required to deliver additional power, and related costs such as congestion costs.

An alternative, more elegant approach to calculating the full value of energy reduction in green buildings (including reduced peak demand reduction) would be to match energy reduction by time of use to the value of incentives being developed to reduce marginal load through demand reduction for three periods – baseload, shoulder periods and peak periods (up to 1000 hours per year). The California Energy Commission report, "Discussion of Proposed Energy Savings Goals for the Energy Efficiency Programs in California" evaluates the potential to achieve substantial energy efficiency savings by providing per kWh financial incentives for these three periods of $0.058/kWh, $0.10/kWh, and $0.167/kWh, respectively. [115] This spread between peak and average prices is used to estimate peak value below. Green building documentation does not provide energy use modeling data that would be required to precisely match green building energy use profiles to these marginal efficiency cost targets.

It appears that there is no recent, comprehensive, and publicly available analysis of the value of peak reduction in decreasing T&D, congestion, and related costs.[116] The most recent robust data, consisting of eleven utility studies, including four in California, is eight to ten years old. Summarized in Appendix D, these studies calculate the value to the grid of reduced peak demand due to on-site electricity generation.[117] On-site generation and on-site energy efficiency are functionally equivalent since both avoid the cost of additional central power generation, distribution facility capacity, and T&D.

These utility studies indicate an average T&D-related peak reduction value of $600 per kW (see Appendix D for calculations). To be very conservative, this report will reduce this value by 50%, providing an estimated value of T&D related benefits of $300/kW. This is almost certainly quite low and warrants further research. Gas peaking plants in California now have a capital cost of

[116] Based on research and a range of interviews with experts at the CEC, PUC, utilities and elsewhere.

[117] As indicated, this data has limitations, which may both exaggerate and undervalue estimates. For example:

1) Only 4 out of 11 studies are from California, and these indicate an average T&D benefit of $510 per kW, lower than the average of $605.
2) The data is 8 to 10 years old. Benefits and costs are likely to have changed somewhat – for example, NIMBY (Not In My Back Yard) concerns and the resulting need to run a larger portion of additional transmission capacity underground have generally increased grid congestion and line expansion costs, indicating that current numbers would probably be higher than those calculated here.
3) Other benefits – described in great detail in the new publication, "Small is Profitable, the Hidden Cost Economic Benefits of Making Resources the Right Size" (RMI, 2002) – were not included in these studies and would tend to increase the value of T&D and related benefits.

On balance these issues would tend to make a comprehensive valuation of T&D and related benefits higher today than these studies indicate.

approximately \$600/kW.[118] Combining the current cost of new marginal generating facilities with \$300 T&D costs results in an estimated total value of \$900/kW for reduced peak demand.

Because of increasing congestion and more cumbersome construction restrictions, T&D and related costs are probably more expensive today than when these studies were done. For example, San Diego Gas & Electric has been planning to build a 31 mile, 500,000 volt transmission line in south Riverside County at an expected cost of \$300 million, or nearly \$10 million per mile –higher than historical costs for large transmission line extensions. However, a PUC administrative law judge recently ruled that the line is not cost-justified over the next five years based on projected electricity demand growth.[119] The explicit recognition of the link between projected electricity demand growth and approval of costly new power lines highlights the potential value of green buildings in reducing or even eliminating the large capital costs of line expansion.

Calculation

As discussed above, green buildings provide an average 30% reduction in energy use, as compared with minimum energy code requirements. For energy costs of \$1.47/ft^2/yr, this indicates savings of about \$0.44/ft^2/yr,[120] with a 20-year present value of \$5.48/ft^2. Energy savings alone exceed the average additional cost of green over conventional construction.

In addition, green buildings provide reduction in peak demand. An important area of research is to develop data needed to better calculate average peak demand reduction. Similarly, USGBC should consider requiring or encouraging that this data be provided in LEED certification documentation. USGBC does not currently require peak capacity analysis to be provided in LEED certification submissions, but output data from several commercially available energy models does provide this information. This report does not calculate savings based on peak capacity reduction. Instead, this report develops a peak reduction value based on data provided on peak energy demand reduction. As discussed above, the limited available data set of green building peak demand reduction for both California and non-California LEED rated buildings indicates a peak demand reduction of 10%.

The value of peak demand reduction can be approximated in several ways, including:

1) Based on California state building experience, a 10% reduction in peak demand for one million square feet of state prisons, hospitals or office buildings amounts to 200 kW, or about \$24,000 per year. On a per ft^2 basis this rule of thumb[121] works out to about \$0.024/ ft^2 per year.[122]

[118] California Energy Commission. "Comparative Cost of California Central Station Electricity Generation Technologies." *Final Staff Report*. June 2003. Available at: http://www.energy.ca.gov/reports/2003-06-06_100-03-001F.PDF, esp. Appendix C.
[119] "SDG&E's Plan for Power Line Dealt Blow," *Energy Info Source, California Energy Report* 10/21/02-11/03/02. Available at: http://www.energyinfosource.com/.
[120] 30% of \$1.47/ft^2/yr total energy costs at 5% discount rate over 20 year term – see Appendix I.
[121] Data provided by the California Department of General Services, November 2002.
[122] Data provided by the California Department of General Services, December 2002.

2) On the basis of an average energy use of 10 kWh/ft^2 per year in state buildings and an average spread in cost between average and peak demand price indicated in recent California Energy Commission estimates for incentives required to reduce marginal load (described above) of $0.067/kWh, it is possible to estimate annual savings from lowered peak power consumption. Assuming peak demand is 8% of all hours, it is estimated, conservatively, that an 0.8 kWh shift from peak power, is worth $0.04 per ft^2 per year.

The two estimates – $0.024/$ft^2$/yr and $0.04/$ft^2$/yr – represent a substantial spread, and indicate the need for better data gathering and more detailed modeling.[123] Adopting a conservative estimated annual savings of $0.025/$ft^2$ results in the 20-year present value of the peak demand reduction attribute of green buildings at $0.31/$ft^2$ ($0.025/year, at 5% real discount rate over 20 years). It is important to emphasize that these are preliminary approximations based on limited data and that more rigorous and thorough modeling should be conducted as a larger data set develops. Despite these limitations, the conclusion indicates that green building energy reduction values include both lowered energy costs and some value of peak demand reduction. The value of peak demand and peak capacity reduction may be higher than estimated here.

Conclusion

Green building energy savings primarily come from reduced electricity purchases, and secondarily from reduced peak energy demand. The financial benefits of 30% reduced consumption at an electricity price of $0.11/kWh are about $0.44/$ft^2$/yr, with a 20-year present value of $5.48/$ft^2$. The additional value of peak demand reduction from green buildings is estimated at $0.025/$ft^2$/yr, with 20-year present value of $0.31/$ft^2$. Together, the total 20-year present value of financial energy benefits from a typical green building is $5.79/$ft^2$. Thus, on the basis of energy savings alone, investing in green buildings appears to be cost-effective.

Comment on Green Buildings and Demand Responsive Pricing

California's shift to dynamic electricity pricing and demand responsive buildings indicates an important future role for green buildings in helping to reduce energy and environmental costs. Several utilities across the country, including Georgia Power Company and Gulf Power have successfully provided financial incentives to customers to cut power consumption as a way to reduce and flatten load and avoid or delay the cost of building and/or operating additional generating capacity. However, California has become the national leader, and is developing dynamic pricing policies and programs to cut costs, increase system efficiency, and create a more intelligent and efficiently used electricity grid.[124]

California is helping residents and businesses install metering and control systems to support increased response to price signals to cut power usage through such measures as load shifting, moving air conditioning to before peak periods, and demand reduction measures such as lowering lighting levels. These measures, now proven ways to cut energy costs by rewarding price

---

[123] Modeling by Gregg Morris of Future Resources Associates based on A-6 Schedule (Figure IV-1) indicates a range of $0.026 -$0.039/ft2/year, indicating that the $0.025/ft/year estimate is conservative (this analysis is available upon request, gmorris@emf.net).

[124] See: Arthur Rosenfeld, Michael Jaske and Severin Borenstein, "Dynamic Pricing, Advanced Metering and Demand Response in Electricity Markets", Hewlett Foundation Energy Series, October 2002. See: http://ef.org/energyseries_dynamic.cfm

responsive customer load management, are being expanded to increase customer, utility, and state benefits. Green buildings are ideal candidates for demand responsive load management because they already typically include relatively advanced metering and energy management systems. If, as seems likely, green building continues to grow very rapidly, these buildings should comprise an important part of California's strategy to expand demand responsive load management. In addition, the USGBC should consider adopting policies that encourage green buildings to include metering and energy management systems. These systems allow buildings to more readily participate in and secure the financial benefits of demand responsive power pricing and grid management.

V. Emissions from Energy

Energy use in California state buildings is over 95% electricity (See Appendix I). The generation of electricity, particularly from fossil fuels, creates a number of harmful emissions. As indicated in Figure IV-2 (Section IV, above), average green building use of conventional energy (and the resulting associated emissions) is on average about 36% lower than conventional buildings. Adding emissions reductions from green power purchases to overall electricity consumption reduction provides a total emissions reduction of 36% compared to conventional buildings.

Value of Pollution Associated with Energy

Energy use in California state buildings and schools is predominantly electricity. Reduction in electricity use means lower emissions of pollutants (due to avoided burning of fossil fuels to generate electricity) that are damaging to human health, to the environment and to property.[125]

Air pollutants that result from the burning of fossil fuels include:

- Oxides of Nitrogen (NOx) – a principal cause of smog.
- Particulates (including PM10) – a principal cause of respiratory illness (with associated health costs) and an important contributor to smog.
- Sulfur Dioxide (SO2 or SOx) – a principal cause of acid rain. (SOx and SO2 are functionally the same for the purposes of this report.)
- Carbon Dioxide (CO2) – the principal greenhouse gas and the principal product of combustion.

Additional fossil fuel related pollutants include reactive organic compounds (ROC) and carbon monoxide (CO). These pollutants are not evaluated here because California power plant emissions represent 0.24% and 0.33%, respectively, of the statewide emissions totals and their values in other building aspects are small.[126] Volatile Organic Compounds (VOCs) may have significant value but are not calculated in this report. A more comprehensive analysis should evaluate the costs of a fuller set of these additional pollutants, including mercury.

There are at least three ways of valuing the costs of air pollution associated with burning fossil fuels:

1) The direct costs of pollution effects on property, health and environment can be calculated and then allocated on a weighted or a site-specific basis.
2) The cost of avoiding or reducing these pollutants can be used as a way to determine market value of pollutants.
3) The market value of pollutants can be used if there is an established trading market.

---

[125] Other forms of power, such as nuclear and hydro, also have environmental costs, though it is not within the scope of this report to evaluate these issues. Note that emissions intensity can vary by time of day, by season and other factors such as peak vs. baseload power (an issue that is addressed elsewhere in this report), although emissions impact is roughly proportional to energy use.

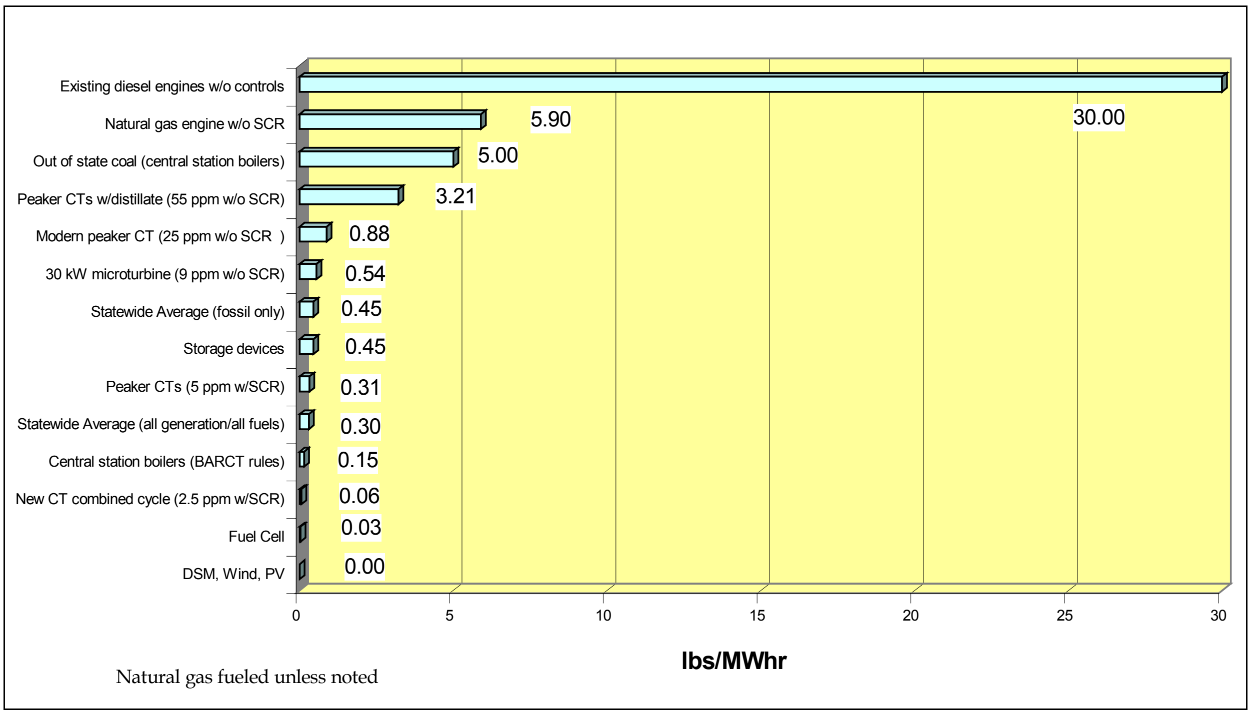
[126] California Energy Commission, "Environmental Performance Report of California's Electric Generation Facilities," July 2001. Available at: http://www.energy.ca.gov/reports/2001-06-28_700-01-001.html.

Each of these approaches has limitations and no one is universally "correct."

Emissions from Energy Use

The emissions reduction from decreased energy use depends on when reduction occurs and what energy source is displaced. Some of the most harmful emissions include NOx, SOx, particulates, and CO2. As indicated in Figure V-1 below, emissions vary vastly from back-up dirty diesel generators (of which the state has 3500 MW[127]) that produce 30 lb of NOx/MWhr,[128] down to zero emissions from renewable energy.[129]

Figure V-1. Generation Technologies Comparative NOx Emissions (lb/MWhr)



Source: "Performance Report of California's Electric Generation Facilities," CEC, July 2001.

Figure V-1 demonstrates that different sources of power are responsible for very different levels of pollution, and consequently different levels of associated health, environmental and property related costs. Benefits derived from the reduction in emissions from green buildings depend in part upon when reductions occur and what type of power (clean or dirty) is displaced. Emissions can vary substantially between California utilities, by season, and by time of use. This report uses an average California emissions factor for electricity to determine the financial value of emissions reductions associated with green buildings. Green buildings also tend to reduce peak

[127] *Ibid.*
[128] *Ibid.*
[129] It should be noted that zero emissions for renewable energy – PV, wind, fuel cells, hydro, etc – refers only to the operation of these generating devices and not to their manufacture.

consumption even more than they reduce overall demand. A more precise estimate would factor in the energy use profile of green buildings and match this to time-of-day power generation and associated pollution. However, this is beyond the scope of this analysis. It should be noted that green buildings can contribute to reducing grid congestion and power reliability and availability problems and can help reduce use of dirty backup/standby generating units. This could be examined in a more detailed analysis.

For a number of reasons – new technology, a shift to renewable energy, improvements in power plant efficiency, emissions control technologies and plant retrofits – emissions of NOx and SOx have dropped sharply and are expected to continue dropping. The CEC Environmental Performance Report notes that, "between 1975 and 2000, NOx and PM10 emissions from power generation declined by 79% and 83% respectively." [130] This decline is summarized in Figure V-2 below.

Figure V-2. Comparison of California Statewide Emissions with Emissions from Power Generation (tons/day)

Pollutant	Source of Emissions	1975	1980	1985	1990	1995	2000	2005 (est.)	2010 (est.)

Source: California EPA, Air Resources Board, Emission Reduction Offset Transaction Cost Summary Report for 2001

The state of California accounts for CO2 inconsistently – the California Inventory of Greenhouse Gas Emissions does not require inclusion of out-of-state generation, whereas the California Emissions Inventory Improvement Program does.[131] Typically, California emissions factors calculated by the Energy Information Administration and others reflect only in-state generation. California imports about 20% of its power from out-of-state, and this power has much higher pollution levels. Total coal generation in 2002 for California was 6220 MW, although 3065 MW or slightly less than 50% was imported.[132] In Los Angeles Department of Water and Power territory, coal imports are even more significant: total coal generation owned by LADWP, for

example, is 2,235 MW – although almost all of it located out-of-state but sold in the California market.[133]

Figure V-3. California Power Emissions Factors from the Tellus Institute (CO_2 Modified)

	Emission Factors (short tons per GWh)		
Pollutant	**1999**	**2010**	**2020**
Carbon Dioxide	308	308	308
Sulfur Dioxide	0.32	0.281	0.244
Nitrogen Oxides	0.404	0.448	0.399
PM-10	0.235	0.2	0.186

Source: Tellus Institute, 2002, modified by Capital E.

Tellus Institute has undertaken analysis of California power emissions, including out-of-state generation. Modified Tellus estimates are used here, principally because they include all power used in California, not just power generated in-state.[134]

These emissions factors developed by Tellus reflect the likely future average mix of electricity generating technologies and fuels used by the California market. They also reflect likely future trends in emission factors under the EIA's projected business as usual scenario through 2020. The Tellus Institute emissions estimates change over time, including a significant increase in CO_2 intensity in 2010 and 2020, to 452 and 490 tons per GWh, respectively. Given California's continuing concerns about pollution, including global warming, and the state's recent commitment to expanded use of renewable energy, it appears that CO_2 intensity is more likely to remain flat than rise, so this report uses the 1999 CO_2 emissions factor throughout the period of calculation. Use of the higher Tellus numbers would indicate larger financial benefits of green buildings.

Estimated Costs Associated with Pollution from Power Generation

Air pollution from burning fossil fuels to generate electricity imposes very large health, environmental and property damage costs. Demonstrated health costs include increased mortality and increased respiratory ailments.[135] The health, environmental and property damages

associated with pollution from burning fossil fuels – commonly referred to as externalities – are only partially reflected in the price of energy. Estimating the costs of externalities is technically difficult, politically problematic, and overall an inexact science. There have been dozens of attempts to estimate the external costs of power generation, but these efforts have not produced consensus. [136]

The California Board of Energy Efficiency (CBEE) developed estimates for environmental adders of $0.0072/kWh, or about 3/4 of one cent per kWh.[137] The CEC sought to determine the damage functions (for health, property and environmental impacts) in their Electricity Reports of 1992 and 1994.[138] In the reports, the CEC expressed reservations about use of this data. Given the lack of consensus on the value of externalities, and changing generation profiles (including steep reductions in some pollutants since the CEC analysis), this report will not rely on these damage functions to calculate the value of emissions reductions.

Instead, this report will rely on market values for traded emissions as the least imperfect of the options available for determining emissions values. These prices reflect actual marginal cost of emissions reductions in relatively liquid and well-established trading markets covering the majority of California's population. For some pollutants, including NOx and SOx, there is a well-established, liquid market and these market prices serve as our best measure of both the marginal cost of emissions reductions and the value society places on them. It is important to note that because the current market for emissions is driven by caps set by regulations, and not the morbidity effects of emissions, it does not directly reflect the externalities of health impacts, and therefore the value of reductions may be significantly understated. Some pollutants, including NOx and PM10, have substantial vehicular sources, and it is possible that the true value of reduced emissions for stationary sources is the same as for mobile ones (although this discrepancy is not recognized in the emissions market). In addition, important pollutants, such as mercury and smaller particulates (e.g. PM2.5) have large adverse health effects that are not addressed in this report. A more comprehensive evaluation of a fuller set of pollutants would end to increase the estimated financial benefits associated with lower conventional energy used in green buildings.

The California Air Resources Board (ARB) compiles and publishes annual data on emissions offset transactions[139] from 35 districts. Figure V-4 contains the reported prices for these offsets.[140] The average value of offsets was used in calculations.

Because there is no cap on CO2 emissions and no California CO2 market, CO2 price-indexes are not compiled and included. To determine CO2 value it is necessary to look at alternative sources.

The Cost of Carbon: Putting a Price on CO2 Emissions

The vast majority of the world's climate change scientists have concluded that anthropogenic emissions – principally from burning fossil fuels – are the root cause of global warming.[141] The United States is responsible for about 22% of global greenhouse gas (GHG) emissions. Of this 22%, the US building sector is responsible for about 35% of US CO2 emissions. CO2 is the dominant global warming gas, equal to about 9% of global anthropogenic emissions. As a recent study notes, US buildings alone are responsible for more CO2 emissions than those of any other country in the world except China.[142]

A report published in July 2002 for the United Nations Environmental Program's Finance Initiatives Climate Change Working Group, *Climate Change and the Financial Services Industry*, warns of the large risks posed by global warming. The report concludes that the "increasing frequency of severe climatic events, coupled with social trends, has the potential to stress insurers, reinsurers and banks to the point of impaired viability or even insolvency." [143] John Fitzpatrick, CFO and Member of the Executive Board of Swiss Re, maintains, "climate change and substantial emissions reductions – like any other strategic global business challenge – ultimately become a financial issue." [144] The United Nations estimates the potential cost of global warming at over $300 billion per year, and insurance firms are becoming concerned about the possibility of lawsuits due to damage from human-induced global warming.[145]

Global warming is recognized as a potentially very costly issue for California, implying a significant value for CO2 reductions in this state. Projected changes in rainfall patterns and snowmelt will likely reduce both available freshwater supplies and the effectiveness of the state's hydropower infrastructure. If California experiences below average rainfall, it could cut the

amount of power that the state gets from hydroelectricity, currently 20% of total power, by up to half.[146]

California's new climate change legislation, passed in October 2002[147] establishes global warming as an issue of legitimate state concern. In addition, previous legislation requires that the value of emissions reductions be considered in developing a present value assessment of solar energy systems for California state buildings.[148] California's building investment and construction programs should reflect this, probably by assigning a dollar value to avoided GHG emissions achieved through better building design. Even if this value is not based on a single, determinative methodology and even if it is low, recognizing the cost of global warming by assigning a dollar value of some amount is preferable to the current practice of assigning no value – effectively $0 – to CO2 reductions. It is also economically efficient for the state to explicitly recognize a value for CO2 in order to ensure a more cost-effective decision making process about building design choices.

It is important to note that because California is a relatively energy efficient state with relatively clean electricity generation, the emissions associated with energy use in California buildings are relatively low. Balancing this, the value of emissions traded in California markets is high relative to the rest of the US.

Market trading rules for CO2 are not yet established and there is no accepted cap on emissions to drive the creation of a California market. Therefore a range of approaches for determining a fair value for CO2 reductions is discussed below.

Assigning a Cost to Carbon

The large energy use of buildings (more than one third of energy used in the economy) has led to extensive analysis of strategies to cut CO2 emissions from this sector. Countries such as Holland are developing specific programs to reduce energy use and associated greenhouse gas emissions from their buildings sector.[149] Innovative legislation passed in 1997[150] in Oregon mandates that new power plants in the state offset a significant portion (roughly 17%) of their CO2 emissions either by avoiding, sequestering or displacing emissions or by funding projects that do the same.[151] To date, this program has funded projects (including those currently under negotiation)

that will result in approximately 3.5 million metric tons of CO2 offsets.[152] Within California, legislation has established the California Climate Action Registry, a voluntary registry for businesses and organizations within California to record annual greenhouse gas emissions and track reductions over time.[153] However, there is currently no mandate for state agencies to participate in the Registry. For California, models indicate that achieving a slowdown in growth of CO2 emissions resulting from building energy use would require state taxes on CO2 of $5 per ton in 2005, rising to $14 per ton in 2020.[154]

Determining a value for CO2 reduction is a difficult proposition. For example, a recent Intergovernmental Panel on Climate Change (IPCC) report cites a range of values between $5 and $125 per ton of CO2.[155] CO2 trading programs in the US are emerging,[156] with the value of trades typically ranging from under $1 up to $16 per ton, with most trades at under $5 per ton, but with a general trend of prices rising. The World Bank has participated in 26 emissions reduction projects, with CO2 trading at $3 to $4 per ton.[157] BP has used a price of $10 per ton for internal trading of CO2.

Despite the wide range of current prices for CO2, there is a widespread perception that CO2 prices will rise as the market demand continues to grow, as more private firms and public entities participate, and as the least expensive tons get bought up first. Many macro models project that to meet significant CO2 reduction targets, CO2 prices must be in the $25-$50 per ton range. The exact clearing price depends to a large extent on the size of emissions reductions sought – a political issue that has yet to be resolved. The EU estimates that to achieve the Kyoto Protocol CO2 targets, CO2 cost will need to be about $30 per ton.[158]

A 2002 A.D. Little (ADL) study for the CEC and the ARB includes a detailed analysis of the value of CO2. This study summarizes CO2 values from four emissions trading firms active in the US and two emissions trading institutions, with prices ranging from $0.10 up to $70 per ton. The individual averages of the six institutions are between $2 and $35, with the average of these averages at $13 per ton of CO2 (note that most trades were at lower prices).

The ADL report concludes by recommending that California adopt a value of $25 per ton of CO2. The CEC estimated that $11 (2002 dollars) must be spent on reforestation to grow enough trees to absorb one ton of carbon dioxide each year.[159] A more recent report, completed by TIAX, LLC for the ARB and CEC completes a similar analysis, but recommends a value of $15 per ton of CO2 emissions.[160]

Given the large range of prices assigned to CO2 by emissions trading markets, policy makers, analysts and others, there is no exactly "right" price per ton of CO2. This analysis recommends that California state agencies adopt a value of $5 or $10 per ton when valuing CO2 emissions. Both of these prices are reasonable figures. These prices are above most current CO2 trades, but well below most medium term estimates for CO2 reduction costs, and below specific price estimates and projections for California. Additional analysis is recommended to arrive at a more thorough valuation of CO2, and this might, for example, include a range of values with probability assigned to each different value. Despite the uncertainties and large credible range of possible prices, some value per ton should be assigned to CO2 for the purposes of calculating the benefits of green buildings, and the relatively conservative prices estimates of $5 and $10 are modeled below.

Conclusion

The average California state building uses electricity at a rate of about 10 $kWh/ft^2/yr$.[161] Converting this to GWh, multiplying by the emissions factors for 2010 from Figure V-3, and then multiplying again by the average prices-per-ton from Figure V-4, yields yearly emissions costs per square foot (Figure V-5). Figure V-6 shows the 20-year PV of a 36% reduction in emissions of the four pollutants discussed above.

Figure V-5. Estimated Annual Cost of Emissions (/ft^2)

Pollutant	Emission Factors (short tons per GWh)	Dollars/ton		Annual Cost of Emissions for 10 kWh	
Carbon Dioxide	308	$5	$10	$0.015	$0.031
Sulfur Dioxide	0.281	$12,809		$0.036	
Nitrogen Oxides	0.448	$27,074		$0.121	
PM-10	0.2	$46,148		$0.092

This report will assume the lower $5 per ton value of carbon, indicating a 20-year PV of $1.18/ft^2 for emissions reductions from green buildings.

VI. Water Conservation

California is facing substantial water shortages that are expected to worsen. Drought years can be particularly difficult on Californians. Urban water users have experienced mandatory rationing, small rural communities have seen wells go dry, agricultural lands have been fallowed, and environmental water supplies have been reduced. Without additional facilities, all of these conditions will only deteriorate with California's projected population increase.[162] Thus, water conservation not only saves money for the end user through reduced utility expenditures, but also saves state water districts the costs of facilities construction and expansion and prevents potential environmental damage.

Green building water conservation strategies typically fall into four categories:

- Efficiency of potable water use through better design/technology.
- Capture of gray water – non-fecal waste water from bathroom sinks, bathtubs, showers, washing machines, etc. – and use for irrigation.
- On-site storm water capture for use or groundwater recharge.
- Recycled/reclaimed water use.

Taken together, these strategies can reduce water use below code/common practice by over 30% indoors and over 50% for landscaping.[163] Of 21 reviewed green buildings submitted to the USGBC for LEED certification (including 6 California buildings) all but one used water efficient landscaping, cutting outdoor water use by at least 50%. Seventeen buildings, or 81%, used no potable water for landscaping. Over half cut water use inside buildings by at least 30%.[164]

Current Practice in California State Commercial and Institutional Buildings[165]

The state's current strategy for water conservation in new or renovated buildings generally does not include measures that exceed federal codes. However, the SBTF has developed a 2-tiered list of sustainable building measures, which includes a number of water efficiency elements.[166] While in theory, new projects should include all feasible water efficiency technologies and strategies, in practice this is not done in most projects.[167] Additionally, state projects are not

mandated to follow California's Model Water Efficient Landscape Ordinance of 1993, even when a project is located in an area where the local utility has adopted it. It is therefore assumed that most state buildings are no more water efficient than other private sector commercial projects in California, and that typical strategies employed to reduce water consumption in private sector projects have a similar impact on California state buildings.

The Cost-Effectiveness of Water Conservation and Demand Reduction Strategies[168]

The potential cost savings of water conservation has been documented in the commercial and institutional sectors. Two 1997 studies – one by the Metropolitan Water District (MWD) and one by the US EPA and the California Department of Water Resources (DWR) attempted to estimate this potential specifically in California.[169] The MWD study found that commercial water use volume could be cost-effectively reduced (average payback – 1.7 years) by approximately 23%. The DWR study came to similar conclusions, finding that a 22% reduction in water use could be cost-effectively generated through conservation strategies. Projected savings by building type include: office buildings - 40%, schools - 21%, and hospitals - 22%.[170] In both studies, the authors note that estimates are conservative, and only include relatively simple technologies and/or implementation strategies and short term paybacks.

Water conservation can take several forms. In an urban commercial or institutional setting, significant savings can be achieved through reductions in outdoor water use – with efficient landscape and irrigation design, automatic rain sensors, and landscape water audit programs to ensure that reductions are met – as well as indoors – with better leak detection, more efficient appliances, and aggressive audits (simply ensuring compliance with existing standards and regulations could result in a 3% demand reduction across the commercial, industrial and institutional sectors).[171]

The cost of urban water conservation programs is typically $500-$750/af of conserved water (1 af = 1 acre-foot = 325,851 gallons).[172] Water can also be conserved by increasing the efficiency of the distribution system. Reducing distribution system losses to 5% through full metering, annual water audits, and systematic leak detection and repair programs would cost an estimated $300/af.[173]

---

[168] Cost-effectiveness is described earlier in the assumptions section, and is consistent with the definition in "BMP Costs and Savings Study: A Guide to Data and Methods for Cost-Effectiveness Analysis of Urban Water Conservation Best Management Practices," prepared for the California Urban Water Conservation Council by A & N Technical Services, Inc, March 31, 1999. It states, "Cost-effectiveness analysis (CEA) is the comparison of costs of a conservation device or activity with its benefits expressed in physical units (for example, $Costs per AF of savings). Cost-benefit analysis (CBA) is the comparison of costs of a conservation device or activity with its benefits, also expressed in dollar terms (for example, $Net Benefits = $Benefits - $Costs)."

Estimated Actual Cost of Water from the State Perspective

A recent empirical study in Canada estimated that the price charged for fresh water was only one-third to one-half the long-run marginal supply cost, and that prices charged for sewage were approximately one-fifth the long-run cost of sewage treatment.[174] Commonly uncounted components of the long-run marginal supply cost include: new marginal water supply expansion and treatment, new marginal wastewater capacity and treatment, and the economic costs caused by environmental damage. Given anticipated population growth and concomitant escalating water demand, these costs are likely to be significant. (For a brief description of California's current water situation including demand, forecasted growth rates, and supply constraints, please see Appendix F). These factors make conservation and demand reduction, as encouraged in green building, all the more attractive – water saved does not need to be treated or disposed.

The California Urban Water Conservation Council (CUWCC) has designed a model to account for all of these factors in determining the total savings of water conservation. Called the Total Society Cost Model,[175] it requires inclusion of all avoided future economic, environmental, and social costs in order to determine a true avoided cost of urban water conservation. It has yet to be implemented by a single agency, perhaps reflecting the fact that determining the true marginal cost of water is difficult.

The following factors contribute to the complexity of determining the true marginal cost of water:

- *Regional Differences*. The current and projected future cost of supplying, treating, delivering and disposing of water vary drastically between and within regions.
- *Future Cost of Water.* To value a water conservation measure today, it is necessary to predict future marginal water costs over the lifetime of the measure. The marginal cost of water in 2012 depends on multiple factors including: demographic changes, weather patterns and public policy choices.
- *Perspective.* Marginal cost depends on perspective. A private building owner, a local utility, a regional utility and a state will all have different marginal cost assumptions.
- *Hard-to-Quantify Environmental Costs*. Although attempts have been made to value some environmental costs (e.g., complying with anticipated regulations), the economic impacts of damages (e.g., habitat destruction, fish losses, local air pollution, greenhouse gas emissions, increased delta salinity, etc.) are generally more difficult to quantify.
- *Unpredictable Political Landscape*. For more than 20 years, California has been taking as much as one million acre-feet per year (1 maf/yr) from the Colorado River above an existing legal limit of 4.4 maf/yr. In January 2003, the Bush administration announced that California would no longer be entitled to this extra water. In 2003, this could mean California will lose as much as 650,000 af of anticipated water supply.[176] This decision will likely increase southern California's marginal cost of water.

- *Climate Change Impacts*. Recent studies suggest that global warming will have a significant impact on California's water resources. It appears there is no available study that projects the impact of climate change on the cost of future water supplies.

Notwithstanding these challenges, two comprehensive studies have been released over the past several years that attempt to determine appropriate marginal water costs for the state. The more recent, *Urban Water Conservation Potential*, was produced by Gary Fiske and Associates for the California Urban Water Agencies (CUWA) in August 2001.[177] It assigns marginal cost numbers to every region of the state for each year from 2000 – 2040.[178]

Figure VI-1 below shows the present value of avoided marginal water costs over a 20 year period based on the CUWA study. *Supply* is the present value of the marginal price the utility would pay to obtain or develop an acre-foot of water each year. *Wastewater* is the present value of the average cost savings - $73.50/af - from the delay of new wastewater facilities construction over the same time period. *Wastewater O&M* is the present value of the average avoided cost to treat new supplies - $13.50/af - over the specified time period. The *Weighted Average Value* is based on anticipated population growth for each region of the state (see Appendix G for calculations).

Figure VI-1. 20-Year Net Present Value of Avoided Marginal Water Supply and Wastewater Treatment Costs to Local Water Agencies in 2003

	Supply (/af)	Wastewater (/af)	Wastewater O&M	Total (/af)
Bay Area	$8,392	$953	$201	$9,546
Central Coast	$4,423	$953	$201	$5,576
Sacramento	$629	$953	$201	$1,783
San Joaquin	$1,944	$953	$201	$3,098
South Coast	$7,920	$953	$201	$9,074
S. Lahontan	$3,683	$953	$201	$4,837
Tulare	$2,046	$953	$201	$3,200
Average	$5,075	$953	$201	
			Weighted Average Value:	**$6,299**

Source: Gary Fisk and Associates for CUWA, Capital E Analysis

The CUWA study highlights the large differences in marginal water costs between regions (Sacramento's current low cost reflects historical access to low cost water sources) and provides a potential baseline for regional marginal water cost analysis.

A second study, *Economic Evaluation of Water Management Alternatives*, was developed by CALFED in October 1999.[179] It makes predictions of marginal water costs in certain regions of California only for the year 2020, and is thus less useful for determining 20-year PV and yearly

[177] Gary Fiske and Associates, "California Urban Water Agencies Urban Water Conservation Potential*."* *Final Report*, August 2001.
[178] It is assumed that wastewater capacity expansion costs would not begin to accrue until 2005 as projects currently being developed should be counted as fixed, sunk costs.
[179] "Economic Evaluation of Water Management Alternatives," prepared for the CALFED Bay-Delta program, October 1999. Available at: http://calwater.ca.gov/Archives/WaterManagement/adobe_pdf/EconomicEvaluationofWaterManagementAlternatives_Oct99.pdf.

marginal water costs than the CUWA study. The "Unconstrained" scenario, CALFED's preferred/expected option of the seven analyzed, is presented in Figure VI-2 below:[180]

Figure VI-2. Marginal Cost Expectations for One Acre-foot of Water in 2020[181]

	CALFED	CUWA
South Coast	$1,045	$628
San Francisco Bay	$1,123	$867
San Joaquin River	$130	$138
Tulare Lake	$211	$143

Source: CALFED, CUWA

While the CALFED numbers are higher than those from CUWA, a more comprehensive assessment of California's water situation would probably reflect marginal cost numbers higher than both for most regions of the state. The California Water Plan Update from 1998[182] cites a number of water development projects and their costs.[183] According to this report, dam construction alone can cost $2.3 billion to deliver an average of 620,000 af/yr from the San Joaquin River. This excludes property, utility relocation and mitigation costs, as well as maintenance and other water delivery costs. Seawater desalinization, often viewed as the upper bound of economically feasible water, costs $1000-2000/af.[184] The following important factors should be included in order to accurately estimate marginal water cost.

Perspective. The marginal cost numbers from the CUWA study are equal to the price the agency pays for water. From the state's perspective, however, there are additional costs of developing new supplies and delivering water to the end user. These costs can be significant. For example, MWD has now begun accepting proposals from its member agencies to develop desalinization facilities. MWD will pay up to $250/af to subsidize the local construction of desalinization plants.[185] From the perspective of the MWD, the marginal cost of this water is $250/af. However, the actual development cost to the local agencies can be up to $2000/af.[186] Assuming an average annual cost of $1150/af suggests a 20-year PV of $14,332/af of new water capacity construction avoided, or more than 2 times higher than the weighted average cost for California indicated Figure VI-1.

---

[180] *Ibid.* Table 8.1.

[181] San Joaquin and Tulare Lake Region numbers are much lower than the Bay Area and South Coast for two primary reasons. First, their marginal need is for agriculture, and agricultural water is much less expensive to develop, treat, and dispose of than urban water. Second, both of these regions are closer to the water sources than the Bay Area and South Coast, sharply reducing pumping costs. Costs include amortized capital and O&M costs for supply measures, plus estimated retail cost components for treatment, distribution and administrative overhead.

[184] *Ibid*, p.6-34.

[185] CUWA study. Op. Cit.

[186] CUWA study. Op. Cit.

Wastewater Treatment Costs. The authors of the CUWA study acknowledge that their wastewater treatment numbers could be refined.[187] The CUWA study assumes that the marginal cost of wastewater treatment will grow at the rate of inflation, as it has, on average, over the past ten years. However, a recent study released by the EPA suggests that future costs will likely rise much more rapidly than in the past.[188] The city of Portland, Oregon, for example, expects wastewater rates to rise by about 7% annually over the next decade, significantly higher than the 2-3% annual increase experienced over the past several years.[189]

Proposition 50 Supply Projects. This initiative, from the November 2002 ballot, requires California to issue $3.4 billion worth of bonds to fund a variety of water projects over the next several years. A portion of the funds is intended for new supply and advanced treatment projects including desalination and reclaimed water.[190] These relatively expensive projects were not included in the marginal cost assumptions in the CUWA study.

Projections of Environmental Costs. Environmental costs beyond those attributed to anticipated regulatory requirements are difficult to quantify. Not surprisingly, the authors of the CUWA study made no attempt to estimate them. Nevertheless, both water supply expansion and marginal consumption have significant potential environmental impacts. These include: wildlife habitat destruction, fish losses, local air pollution and climate change impacts, among others.[191]

In addition, multiple studies suggest that global warming will likely alter precipitation patterns in the state. A recent report by the Pacific Institute summarized the results of nearly 1,000 peer-reviewed studies on climate change. The report states "with very high confidence":

> *It is likely that reductions in snowfall and earlier snowmelt [caused by global warming] and runoff would increase the probability of flooding early in the year and reduce the runoff of water during late spring and summer. Basins in the western United States are particularly vulnerable to such shifts*.[192]

Available at: http://www.gcrio.org/NationalAssessment/water/water.pdf. A similar UCS study finds that more precipitation will fall as rain, rather than snow, causing massive flooding in the spring and droughts by late summer. Reduced summer runoff of fresh water would also increase summer salinity in San Francisco Bay, requiring less diversion in order to meet ecosystem and bay water quality needs. Christopher Field, "Confronting Climate Change in California: Ecological Impacts on the Golden State*,*" *Union of Concerned Scientist*, 1999.
Available at: http://www.ucsusa.org/publication.cfm?publicationID=7.

According to the California Climate Change Registry, climate change in California will also likely cause the following: a sea level rise of 4-35 inches by 2100, severe salt-water intrusion into coastal aquifers, and greater air pollution.[193]

Exclusion of Reclaimed Water Projects. Reclaimed water projects provide an increasingly large share of "new" water supply. In the Bay Area, for example, reclaimed water is expected to account for 50% of new supply over the next twenty years.[194] Reclaimed water projects typically cost $600-$1100/af – higher than the marginal costs numbers presented in the CUWA study in *every* region of the state. At an average cost of $850/af, the 20-year PV for avoiding new reclaimed water projects is about $10,593/af, or almost 2 times larger than CUWA estimates for the Bay Area.

This report will assume that actual costs are two times higher than indicated by CUWA data, for a state average 20-year PV of $12,598/af. For the reasons described above, even this adjusted cost estimate is likely to be low. Additional work needs to be conducted to obtain more accurate full cost numbers.

Conclusion

Green buildings are designed to conserve water. Taking the avoided cost of water to be only the average retail price paid by state agencies to local utilities, the literature suggests that there is considerable potential for cost-effective water conservation strategies in new and renovated building projects in many regions of the state. However, the actual value of water conservation to the state is not the avoided cost of retail water rates. Rather, it is the region-specific added cost of new marginal water supplies.

The CUWA study cited above advances knowledge of the marginal costs of new water supplies. But it is clear that additional work needs to be done to determine more realistic numbers. More comprehensive assumptions will likely yield higher marginal costs, and thus higher potential savings. Nevertheless, the CUWA study is a good basis for determining average statewide costs, and can be adjusted upward to reflect actual recent water costs.

The modified CUWA findings were applied to a hypothetical new state building project to determine potential savings and include this and a cost doubling to reflect the higher actual costs discussed above. This provides a 20-year PV of $0.51/ft^2 for water savings from green buildings. These costs are very likely conservative (low) for reasons discussed above. Please see Appendix G for the detailed calculations.

This investigation provides a conservative estimate for the value of water savings from green building, but also indicates that more research and analysis needs to be done.

VII. Waste Reduction

Nearly 60% (over 21 million tons in 1998) of waste in the state of California comes from commercial (i.e. non-residential) buildings.[195] Additionally, 57% of the construction and demolition (C&D) debris nationally comes from the non-residential sector.[196] California state buildings generally fall within this category.

Waste reduction strategies such as reuse and recycling, as promoted in green buildings, help to divert some waste from being disposed of in landfills. Diversion strategies result in savings associated with avoided disposal costs as well as in reduced societal costs of landfill creation and maintenance. In addition to diverting waste from landfills, recycling and reuse can catalyze further economic growth in industries that reprocess diverted waste and use recycled raw materials.

Green building waste reduction strategies can occur at time of construction and throughout the life of the building.

Construction waste reduction options include:

- Reuse and minimization of construction and demolition (C&D) debris and diversion of C&D waste from landfills to recycling facilities.
- Source reduction, e.g., (1) use of building materials that are more durable and easier to repair and maintain, (2) design to generate less scrap material through dimensional planning, (3) increased recycled content, (4) use of reclaimed building materials, and (5) use of structural materials in a dual role as finish material (e.g. stained concrete flooring, unfinished ceilings, etc.).
- Reuse of existing building structure and shell in renovation projects.

Building lifetime waste reduction includes:

- Development of indoor recycling program and space.
- Design for deconstruction.
- Design for flexibility through the use of moveable walls, raised floors, modular furniture, moveable task lighting and other reusable building components.

Together, these strategies can have a dramatic impact on reducing landfill disposal. C&D diversion rates have reached as high as 97% on individual state of California projects, and are typically at least 50-75% in green buildings.[197] C&D waste impacts vary greatly depending on the type of building project and whether it is new construction, renovation, or construction on already developed land.

[197] California State and Consumer Services Agency and Sustainable Building Task Force. "Building Better Buildings: A Blueprint for Sustainable State Facilities." December 2001. P.16.

Of 21 green buildings submitted to USGBC for certification, seventeen, or 81%, reduced construction waste by at least 50%, while 38% reduced construction waste by 75% or more.[198] Renovated projects can often utilize 75-100% of a building envelope and shell (excluding windows) and up to 50% of non-shell elements (walls, floor systems, etc.).[199]

Designing indoor recycling systems encourages recycling as part of a building's operational practices. Moveable walls, raised floors, modular furniture, and moveable task lighting can reduce the costs and wastes associated with reconfiguring office spaces (similar to saved churn costs of "Underfloor Air" – see Section IX).

It is clear that green buildings recycle and divert substantially higher levels of waste, and incorporate greater amounts of recycled or "re-used" materials than conventional buildings. However estimating the relative increases in waste recycling, diversion and use of green buildings compared with conventional buildings is difficult and tenuous.

Current Practice in California State Commercial and Institutional Buildings

Currently, there is no standard practice for incorporating all the waste reduction elements into state construction projects, although efforts are underway in each individual category.

C&D diversion requirements are incorporated into state contracts through the use of building performance standards and the Tier sustainable building measures checklists, which specify technologies that should be or can be used in new buildings. Tier 1 requires that all projects develop a recycling plan that results in the diversion of 50% or more of C&D materials, and Tier 2 encourages project teams to consider diverting 75% or more (if economically feasible). Although required, there is little evidence to date that indicates either is regularly done for state projects.[200]

The Tier 1 list also requires projects to "provide for dedicated space in and outside the building for the collection, storage, and loading of recyclable materials." Unfortunately, information is not readily available to indicate how often dedicated recycling space is actually included in space designs. AB 75 does require state agencies and large state facilities (college campuses and prisons) to divert 25% of generated solid waste from landfills by January 1, 2002 and to achieve a 50% diversion rate by January 1, 2004.[201] Regardless of whether or not dedicated space is included in design, state agencies are required to implement recycling programs and many recycling programs are in place and being enhanced to reach this goal.

With respect to the purchase of recycled content products, there is a state mandate through the State Agency Buy Recycled Campaign[202] (SABRC) that requires state agencies to meet recycled content requirements for products in each of 12 categories.[203] Contractors for state agencies must also supply recycled content products that meet the SABRC requirements. Although SABRC has

[203] See: http://www.ciwmb.ca.gov/BuyRecycled/StateAgency/Buying.htm.

been in place for approximately 14 years, Block 225 of the Capitol Area East End Project was the first construction project to attempt to implement the mandate. While not all materials used in Block 225 were SABRC compliant, this project was invaluable in helping the state to develop specification language, reporting procedures, and forms that will assist future state projects in their efforts to increase the use of recycled content products.[204] The Tier 1 list does include requirements for the use of recycled content products, promoting the incorporation of these materials into projects when appropriate. Because the checklists were developed considering only material first costs, those products deemed cost-effective are fairly limited.

Since the enactment of the 1989 California Integrated Waste Management Act (AB 939),[205] waste diversion in California has been steadily increasing – from 17% in 1990, to 25% in 1995, to 48% in 2002.[206]

The Retail Cost of Disposal and Diversion

Retail collection and removal fees in California currently range from \$90 – \$150/ton for disposal (including an average tipping fee of \$34/ton)[207] and from \$120 – \$200/ton for recycling.[208] These are the fees paid by customers to waste management companies for waste collection and removal, and are associated with curbside recycling, not generally applicable to many commercial businesses. Higher fees for recycling collection probably result from the necessity to sort and collect separately different types of recycled waste. The range reflects many factors including: tipping fees, type of recycled material, recycled product markets and infrastructure, labor costs, and subsidies. Additionally, hauling costs may be higher for diversion/recycling because the waste must be transported farther in order to be processed.

Because of the relative high quality of many recovered building materials, well established markets, and lower collection costs, C&D recycling is generally less expensive per ton than curbside residential or commercial service. For example, C&D recyclers in the Sacramento region will accept concrete and asphalt for free and clean wood waste for less than \$10 per ton,[209] while the Sacramento County Landfill charges \$26 per ton[210] (hauling costs are not included in these figures). In this instance where the first cost of recycling is less than the first cost of disposal there is a direct financial incentive to divert materials for recycling and reuse.

Estimated Actual Cost and Benefits of Landfill Diversion

From the perspective of the state, the value of diverting materials from landfills should include all quantifiable benefits that accrue to the state. These include direct economic benefits as well as avoided environmental costs.

Direct Economic Value

Two recently published studies have quantified the economic costs and benefits of landfill disposal and diversion in California. The Department of Agriculture and Resource Economics at UC Berkeley (UCB), in conjunction with the California Integrated Waste Management Board (CIWMB), published the first study in April 2001.[211] The second, conducted by the National Recycling Coalition (NRC), was released in July 2001.[212] It is important to note that these studies deal with the economic impacts of waste diversion in general and are not specific to C&D diversion. These studies have been included to show the positive economic impact of diversion as compared to disposal.

The UCB study used 1999 data to compare the economic impacts of waste disposal to diversion in six California regions. For both disposal and diversion, the study calculated Total Sales generated from waste and four multiplier effects:

- *Total Output* – a measure of how the disposal/diversion sector influences total economic activity including direct (e.g., collection of wastes), indirect (e.g., collection/recycling equipment manufacturers, other support businesses) and induced impacts (e.g., engineers/consultants) – not including environmental costs.[213]
- *Total Income* – a measure of the total income earned by all persons in the economy attributed to disposal/diversion.
- *Total Value Added* – a measure of the increase in the value of goods sold by all sectors of the economy, minus the costs of inputs.[214]
- *Number of Jobs* – the number of jobs created by disposal/diversion activities.

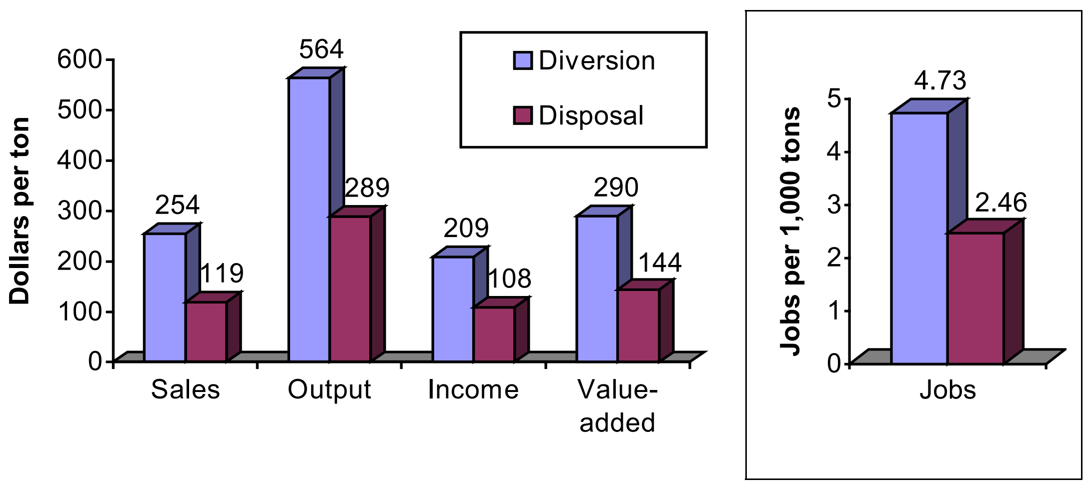
213 Total Output includes both Total Income and Value Added.

214 Value Added also includes tax revenues.

Figure VII-1. Value of Diversion vs. Disposal in UCB Study



Source: Goldman and Ogishi, April 2001

In general, the UCB study found that total economic impacts from diversion are nearly twice as large as the impacts from disposal. One additional ton of waste disposed in a landfill in California generates $289 of total output in the state economy. One additional ton of waste diverted as recyclables generates an average of $564. Figure VII-1 above shows that only 2.46 jobs are created for every 1,000 tons of waste disposed, while 4.73 jobs are created for waste diverted as recyclables. The study also found that regional variation is significant. The Central Valley's total output impacts are nearly $350 per ton greater when waste is diverted, while the Eastern region is the only place in the state where, due to currently limited infrastructure to support recycling businesses, the average economic impacts for diversion are less than the impacts for disposal.[215]

The NRC study has a broader scope than the UCB study. It compares diversion to other sectors of the economy and shows how the economic impacts from diversion in California fit within the nationwide economy. It also uses different assumptions, input data and methodologies. Despite the differences, the resulting economic impacts per diverted ton are quite similar.

Averaging the results of the two diversion studies show that when material is diverted rather than disposed in a landfill, the marginal impacts are worth:[216]

- $325 per ton in Output Impact
- $70 per ton in Income Impact
- $111 per ton in Value Added Impact
- 2.15 jobs per 1,000 tons

---

215 George Goldman and Aya Ogishi, "The Economic Impact of Solid Waste Disposal and Diversion in California." Paper presented at the *Western Agricultural Economic Association Meeting*, Logan Utah, July 20, 2001, p. 14. Available at: http://are.berkeley.edu/extension/EconImpWaste.pdf.

216 These numbers are based on data from "Two Studies on the Economic Impacts for Diversion: A Brief Review by Board Staff" (unpublished document from the CIWMB).

The figures are intended to quantify the economic impacts for the period of one year – the year in which the waste is either disposed of or diverted. They are not 20-year PV numbers. Both studies may under-estimate the full marginal value of diversion. In the Berkeley study, for example, only data from manufacturers that use recycled materials extensively (as identified by the 1997 Census of Manufacturers) were included. In addition, the Census data set does not include all industries. The value of source reduction and reuse were also not included in the study, nor was the value of some common materials such as tires. Consideration of these factors would likely increase the value of diversion.

Avoided Environmental Costs

While no study completed to date has examined and quantified the environmental benefits of recycling in California, several have investigated the subject in other states. The most comprehensive study was conducted in Massachusetts in 2000. The study found average total net environmental benefit of recycling at $63 per ton. According to the study, diversion has two primary benefits compared to disposal:[217]

1) Fewer hazardous substances and greenhouse gases are emitted when products are manufactured with recycled materials instead of virgin wood, metal and petroleum resources.[218]
2) Fewer hazardous substances and other pollutants are released when materials are collected for recycling instead of landfill disposal or incineration.

Just as the economic impact described in the UCB and NRC studies must be further refined to create a more meaningful number, this environmental estimate should be adjusted to reflect California-specific conditions. In addition, projected costs for long-term maintenance of environmental hazards associated with landfill degradation should also be considered.

Conclusion

As discussed above, estimating financial benefits of waste reduction, diversion and recycling from green buildings relative to existing buildings is difficult. At present, the AB75 baseline for waste diversion for California state agencies is 25%, set to increase to 50% in 2004. Although this does not apply directly to specific building construction projects, construction and demolition debris diversion do factor into the overall state agency calculation. Currently, no data exist to indicate whether or not these goals are being met relative to construction projects. However, diversion rates in excess of 75% are commonly met on projects where project managers enforce the Tier 1 & 2 requirements for waste diversion. Improved reporting of diversion and disposal data for state projects would significantly improve the ability to estimate the waste reduction benefits of green buildings.

[217] Lisa Skumatz and Jeffrey Morris, "Massachusetts Recycle 2000: Baseline Report," prepared for the Commonwealth of Massachusetts Executive Office of Environmental Affairs (EOEA) Recycle 2000 Task Force, December 1998.

[218] Estimates of net benefits of GHG reductions are based on US EPA, "Greenhouse Gas Emissions from Management of Selected Materials in Municipal Solid Waste, Final Report," September 1998, Exhibit ES-4. Available at: http://yosemite.epa.gov/oar/globalwarming.nsf/UniqueKeyLookup/SHSU5BVP7P/$File/r99fina.pdf.

It is possible, with a set of tentative assumptions, to estimate waste benefits associated with green buildings. This report uses the numbers from the UCB and NRC/REI studies, combined with the environmental benefit from the Massachusetts study, to calculate rough conservative values for C&D diversion in for new construction as well as demolition of pre-existing structure before construction:

- $0.03/ft^2 or $3,000 per 100,000 ft^2 building for construction only.
- $0.14/ft^2 or $14,000 per 100,000 ft^2 building for construction preceded by demolition.

Since green buildings attempt to use some of the pre-existing building envelope, it is probable that diversion percentages for the second case will be higher than estimated in this analysis. The details of these calculations are included in Appendix H.

In the absence of good data on present rates of waste diversion in green and conventional buildings during both their construction and operation, it is impossible to quantify the relative advantages of either one. However, it appears probable that the green building waste reduction advantage would not exceed about $0.50/ft^2, because of California's already aggressive waste reduction targets (as set forth in AB 75 and AB 989) – the effectiveness of which is evidenced by the increase in waste diversion from 17% in 1990 to 48% in 2002.[219]

A more thorough study is needed to obtain more realistic financial cost estimates of diversion versus disposal and to generate a California-specific value for the environmental benefits of construction and demolition waste diversion and recycling.

VIII. Productivity and Health

California's Executive Order D-16-00, which established the Governor's sustainable building goals, includes the statement that sustainable building practices should "enhance indoor air quality; and improve employee health, comfort and productivity,"[220] indicating that health and productivity benefits should be explicitly recognized in the state's building design and funding decisions.

This section contains a brief overview of what is known about health, human comfort and productivity in relation to green building design and operation. The conclusion contains a reasonable and conservative estimate for the monetary value of productivity gains in green buildings. Health and productivity issues, often addressed separately, are combined here because both relate directly to worker well-being and comfort and both can be measured by their impacts on productivity.

The relationship between worker comfort/productivity and building design/operation is complicated.[221] There are thousands of studies, reports and articles on the subject. This report relies in large part on recent meta-studies that have screened tens or hundreds of other studies and have evaluated and synthesized their findings.

Potential Savings

The cost to the state of California for state employees is ten times larger than the cost of property. The following chart (Figure VIII-1) and supporting data (see Appendix I) represent state costs for 27,428 state employees in 38 state-owned buildings. Note that operations and maintenance (O&M) costs are allocated 44% for labor and 56% for property related expenses.[222] Average annual employee costs ($66,478 in salary and benefits - $65,141 - plus allocated operations and maintenance costs - $1,337), are 10.25 times larger than the cost of space per employee ($6,477).[223] Thus, measures that increase employee costs by 1% are equivalent, from a state cost perspective, to an increase in property related costs of about 10%. *In other words, if green design measures can increase productivity by 1%, this would, over time, have a fiscal impact roughly equal to reducing property costs by 10%.*

---

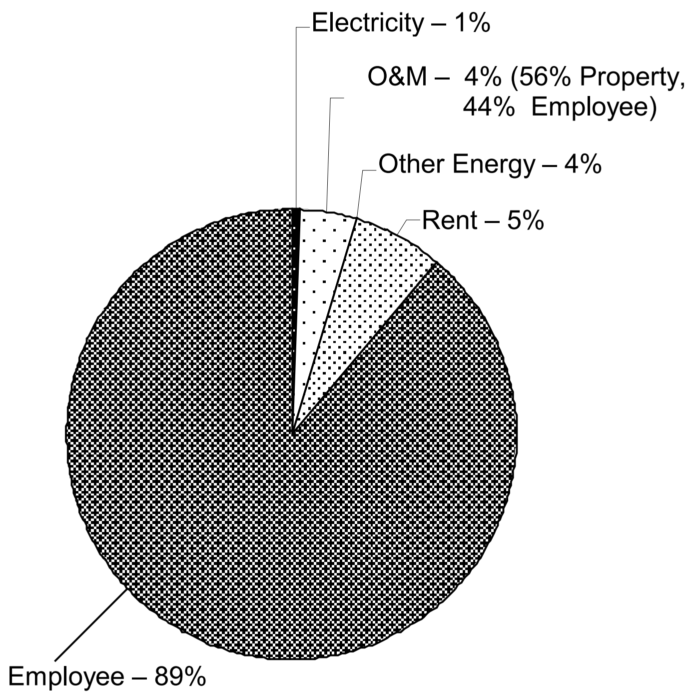
[220] State of California. Governor's Executive Order D-16-00, August 2000.
Available at: http://www.governor.ca.gov/state/govsite/gov_homepage.jsp.

[221] One approach to address this complexity is offered by comprehensive building performance scoring tools for evaluating building design and operation benefits. One example of this type of scoring methodology is called the Balanced Scorecard. This approach evaluates four categories of building performance: Financial Results (cost of absenteeism, turnover, etc), Business Processes (innovation, product quality, etc), Customer Satisfaction (stakeholder relations - including public image and local economic impact), and Learning and Growth (human capital development - including work satisfaction and productivity). These kinds of broad systems approaches are valuable for explicitly demonstrating how green buildings support health, productivity and other benefits and meeting larger corporate objectives. However, these types of approaches are less helpful for quantifying the benefits of green building design. See for example: http://www.balancedscorecard.org/bscand/bsckm.html.

[222] Operations and Maintenance cost ($3,039) are allocated 44% for labor and 56% for property related expenses. Data provided by the California Department of General Services, Real Estate Services Division. December 2002.

[223] See Appendix I.

Figure VIII-1. Costs in California State Employee-Occupied Office Buildings
(December 2001 - September 2002 with projections for November-December 2002)



Source: Real Estate Services Division of Department of General Services.[224]

Increased productivity is closely linked to improved worker health. Companies with a demonstrably healthier work environment can also experience reduced insurance premiums – a topic covered in Section X.

The Building-Productivity Link

There is growing recognition of the large health and productivity costs imposed by poor indoor environmental quality (IEQ) in commercial buildings – estimated variously at up to hundreds of billions of dollars per year. This is not surprising as people spend 90% of their time indoors, and

---

224 Data provided by the California Department of General Services. November 2002. Note that these include state owned buildings leased to state agencies and that on average these rental rates are slightly below market average – perhaps by about 10%. The data were not adjusted to account for this (by about 3%) because doing so has no significant effect on calculations or conclusions. Conditioned area per employee is assumed to be $225ft^2$ – the number indicated by the California Department of General Services, Real Estate Services Division. This is significantly below the aggregate data summarized in Appendix I, provided by DGS, reflecting the fact that a substantial portion of building space is not conditioned occupied. Annual average energy cost is about \$1.60, conservatively projected to decline to $\$1.47/ft^2$. (Also see discussion of this data in Energy Use section.)

the concentration of pollutants indoors is typically higher than outdoors, sometimes by as much as 10 or even 100 times.[225]

Measuring the exact financial impact of healthier, more comfortable and greener buildings is difficult. The costs of poor indoor environmental and air quality – including higher absenteeism and increased respiratory ailments, allergies and asthma – are hard to measure and have generally been "hidden" in sick days, lower productivity, unemployment insurance and medical costs.

The discussion of IEQ and productivity issues in industry publications has expanded rapidly in the last decade to become a common theme, and has spilled over into popular media. Business Week's cover for its June 5, 2000 issue features a picture of a large menacing office building to accompany the feature story: "Is Your Office Killing You? The Dangers of Sick Buildings." [226] The article cites potential benefits of up to $250 billion per year from improved indoor air quality in US office buildings.

There are now hundreds of published testimonials about the health and productivity benefits that result from adopting green design strategies. For example:

- William Pape, the cofounder of VeriFone, reports that eighteen months after VeriFone employees began working in a building retrofitted to cut indoor pollutants and improve indoor environmental quality, absenteeism rates were down 40% and productivity was up by more than 5%. Pape notes that healthy workplaces have "done more to boost productivity than all the bandwidth in the world." [227]
- Gary Jay Saulson, the Senior VP and Director of Corporate Real Estate for PNC Realty Services, describes the benefits of the LEED Silver PNC Firstside Center building in Pittsburgh as follows: "people want to work here, even to the point of seeking employment just to work in our building. Absenteeism has decreased, productivity has increased, recruitment is better and turnover less." Two business units experienced 83% and 57% reductions in voluntary terminations after moving into the new Firstside facility.[228]

The relationship between green building strategies and productivity has been studied and documented extensively. There are number of substantial databases that aggregate and screen studies on the relationship between specific building performance attributes and productivity and worker well-being.[229]

[229] The Rocky Mountain Institute has been a pioneer in developing and publishing studies on green buildings and productivity, including both original research and reviews of studies on the impact of green buildings on productivity, sales and other worker performance measures. See Rocky Mountain Institute website, "Buildings & Land," Available at: http://www.rmi.org/sitepages/pid174.php. These include:

What Do Tenants Want?

Given the large impact that poor IEQ has on the health and comfort of office workers, it is not surprising that recent surveys of workers suggest that IEQ is one of the most important components of job satisfaction. For example, the study, *What Office Tenants Want: 1999 BOMA/ULI Office Tenant Survey Report*[230] is based on questionnaires from 1800 office tenant surveys in 126 metropolitan areas. Conducted by the Building Owners and Managers Association (BOMA) and the Urban Land Institute, the study affirms that office tenants highly value comfort in office buildings. Survey respondents attributed the highest importance to tenant comfort features, including comfortable air temperature (95%) and indoor air quality (94%). Office temperature and the ability to control temperature are the only features that were both "most important" and also on the list of things with which tenants are least satisfied. The BOMA/ULI study found that the number one reason that tenants move out is because of HVAC heating/cooling problems.

The BOMA/ULI survey found that office tenants also highly value intelligent building features. These include modern energy-efficient HVAC systems and automatic sensors for lighting. According to the BOMA/ULI study, over 75% of office buildings do not have these intelligent features. The survey found that 72% of tenants who want an intelligent feature would be willing to pay additional rent to have the feature made available.

This and other studies make it clear that a high percentage of office tenants are dissatisfied with the indoor air quality (IAQ) and comfort of their work environment and express a willingness to pay for a greener, more comfortable and productive one.

California has developed its own requirements for IAQ that differ from and are in some ways more stringent than IAQ prerequisites contained in LEED. Although the new California IAQ requirements have been adopted for use in the East End complex, they are not required in new construction and have, as yet, not been generally applied. Until these new standards are incorporated, the LEED approach to IAQ offers a significant improvement over current California practices.

While the full range of design practices encouraged by LEED is available in Appendix A, the following are some relevant attributes common in green buildings that promote healthier work environments:

1) Much lower source emissions from measures such as better siting (e.g., avoiding locating air intakes next to outlets, such as parking garages, and avoiding recirculation), and better building material source controls (e.g., required attention to storage). Certified and Silver level green buildings achieved 55% and Gold level LEED buildings achieved 88% of possible LEED credits for use of the following:[231]

    a. less toxic materials
    b. low-emitting adhesives & sealants
    c. low-emitting paints
    d. low-emitting carpets
    e. low-emitting composite wood
    f. indoor chemical & pollutant source control

2) Significantly better lighting quality including: more daylighting (half of 21 LEED green buildings reviewed provide daylighting to at least 75% of building space[232]), better daylight harvesting and use of shading, greater occupancy control over light levels and less glare.

3) Generally improved thermal comfort and better ventilation – especially in buildings that use underfloor air for space conditioning (see Section IX).

4) Commissioning, use of measurement and verification, and CO2 monitoring to ensure better performance of systems such as ventilation, heating and air conditioning (see Section IX).

The links between specific LEED credits and productivity are reviewed in other publications.[233]

One of the most authoritative studies to date quantifying potential health and productivity benefits from improved indoor environments was undertaken by William Fisk, head of the Indoor Environment Department at Lawrence Berkeley National Laboratory, and colleagues. Their findings, estimated across the US, are summarized below and reflect analyses and syntheses of a large number of prior studies. Fisk et al. divided the health benefits provided by better buildings into four principal areas: acute respiratory illness, allergies and asthma, sick building syndrome symptoms, and direct productivity gains. A summary of the rationale and supporting data and assumptions underlying Fisk's calculations is included as Appendix J.

Figure VIII-2. Potential Productivity Gains from Improvements in Indoor Environments

Source of Productivity Gain	Potential Annual Health Benefits	Potential U.S. Annual Savings or Productivity Gain (2002 dollars)
1) Reduced respiratory illness	16 to 37 million avoided cases of common cold or influenza	\$7 - \$16 billion
2) Reduced allergies and asthma	8% to 25% decrease in symptoms within 53 million allergy sufferers and 16 million asthmatics	\$1 - \$5 billion
3) Reduced sick building syndrome symptoms	20% to 50% reduction in SBS health symptoms experienced frequently at work by ~15 million workers	\$10 - \$35 billion
4) Sub-total		*\$18 - \$56 billion*
5) Improved worker performance from changes in thermal environment and lighting	Not applicable	\$25 - \$180 billion
6) Total		*\$43 - \$235 billion*

Adapted from: William Fisk, "Health and Productivity Gains from Better Indoor Environments"[234]

The first two sources of productivity gain outlined in Figure VIII-2 are only partially attributable to the work environment, so this report assumes that potential health benefits are therefore reduced to a range of \$12 to \$45 billion annually. Productivity benefits from both health improvement and from improvement in thermal environment and lighting are reduced to a range of \$35 to \$225 billion. Note that there are other, less substantial sources of potential health related benefits that are not included in Figure VIII-2, making these estimates of benefits potentially low.

Assuming a low value of \$25 billion, this translates into \$385 in direct health improvement potential for each of the 65 million full time office workers and teachers in the US.[235] If one third of these benefits can be achieved in a green building, this translates into about \$130 per year in health-related financial benefits. With 225 ft^2 in average space per worker, this suggests a potential annual productivity gain of $\$0.58/ft^2$.

If we assume a mid-range value of \$140 billion in potential productivity benefits (line 6 in Figure VIII-2), and assume that 1/3 of these benefits could be achieved from respiratory health benefits

and thermal and lighting improvements in green buildings, this translates into about $718 per worker per year. This suggests a potential annual productivity gain of $3.19/ft^2$ per worker, or slightly over 1% per year.

A review published by ASHRAE compares commonly used measures of productivity with HVAC system performance. In the study, the authors evaluate 262 references and feature the 53 most rigorous and significant ones. These demonstrate a positive correlation between measures common to green buildings and productivity, absenteeism, and related issues.[236]

A National Science and Technology Council project entitled *Indoor Health & Productivity* was established to collect and communicate research findings relating workplace attributes – including lighting, thermal comfort, air quality and ventilation – to human health and productivity. The database contains over 900 papers from more than 100 journals and conferences. There are abstracts for about 700 of these articles, and the entire database is searchable by fields such as author and category (e.g., acoustics, humidity, ventilation) or by keywords such as sick building, visual comfort or HVAC.[237] There is a very large body of technically sound studies and documentation linking health and productivity with specific building design operation attributes – e.g., indoor air quality and tenant control over work environment, including lighting levels, air flow, humidity and temperature. It is clear that green building measures that improve these attributes increase worker comfort, health, well-being and measured productivity.

Two studies of over 11,000 workers in 107 European buildings analyzed the health effect of worker-controlled temperature and ventilation. They found significantly reduced illness symptoms, reduced absenteeism and increases in perceived productivity over workers in a group that lacked these features.[238]

Seattle City Light has compiled over 30 projects that document productivity, increased retail sales and increased student learning resulting from incorporation of green design elements.[239] The program intends to create a database documenting the impact of green features on worker comfort, health, productivity and related measures for all municipal buildings that meet or exceed LEED Silver level and is preparing to release a study of a dozen Seattle green buildings, including costs and benefits.

Productivity Benefits for Specific Worker Control/Comfort Upgrades

One of the leading national centers of expertise on the benefits of high performance buildings is the Center for Building Performance at Carnegie Mellon University. The Center's Building Investment Decision Support (BIDS) program has reviewed over 1000 studies that relate

technical characteristics of buildings, in areas such as lighting and ventilation, to tenant responses, such as productivity. Of these studies, the Center has identified 95 that are sufficiently rigorous and quantitative to meet their criteria for inclusion in the BIDS database and decision making tool, making it perhaps the most valuable database of its kind.[240]

Collectively, these studies demonstrate that better building design and performance in areas such as lighting, ventilation and thermal control correlate to increases in tenant/worker well-being and productivity. The BIDS data set includes a number of controlled laboratory studies where speed and accuracy at specific tasks was measured in low and high performance ventilation, thermal control and lighting control environments. These studies used a range of speed and accuracy performance measures including: typing, addition, proof reading, paragraph completion, reading comprehension, and creative thinking.[241]

Increases in tenant control over ventilation, temperature and lighting each provide measured benefits from 0.5% up to 34%, with average measured workforce productivity gains of 7.1% with lighting control, 1.8% with ventilation control, and 1.2% with thermal control. Additionally, measured improvements have been found with increased daylighting, as discussed in the following section.

Figures VIII-3, VIII-4 and VIII-5 on the subsequent pages were supplied by the Department of Architecture at Carnegie Mellon University. They represent ongoing research, and as such should be considered interim.[242]

Carnegie Mellon's BIDS™, for Building Investment Decision Support, is a case-based decision-making tool that calculates the economic value added of investing in high performance building systems, based on the findings of building owners and researchers around the world.

[241] Communication with Vivian Loftness, CMU, February 2003.

[242] Data extracted from BIDS™. Carnegie Mellon University Department of Architecture. February 2003. (Vivan Loftness).

Figure VIII-3: Increased Ventilation Control

The 13 studies summarized below by CMU show a consistently significant positive correlation between increased control over ventilation and increased productivity – ranging between 0.5 % and 11%, with most studies clustering around 1% and an average of 1.8%.

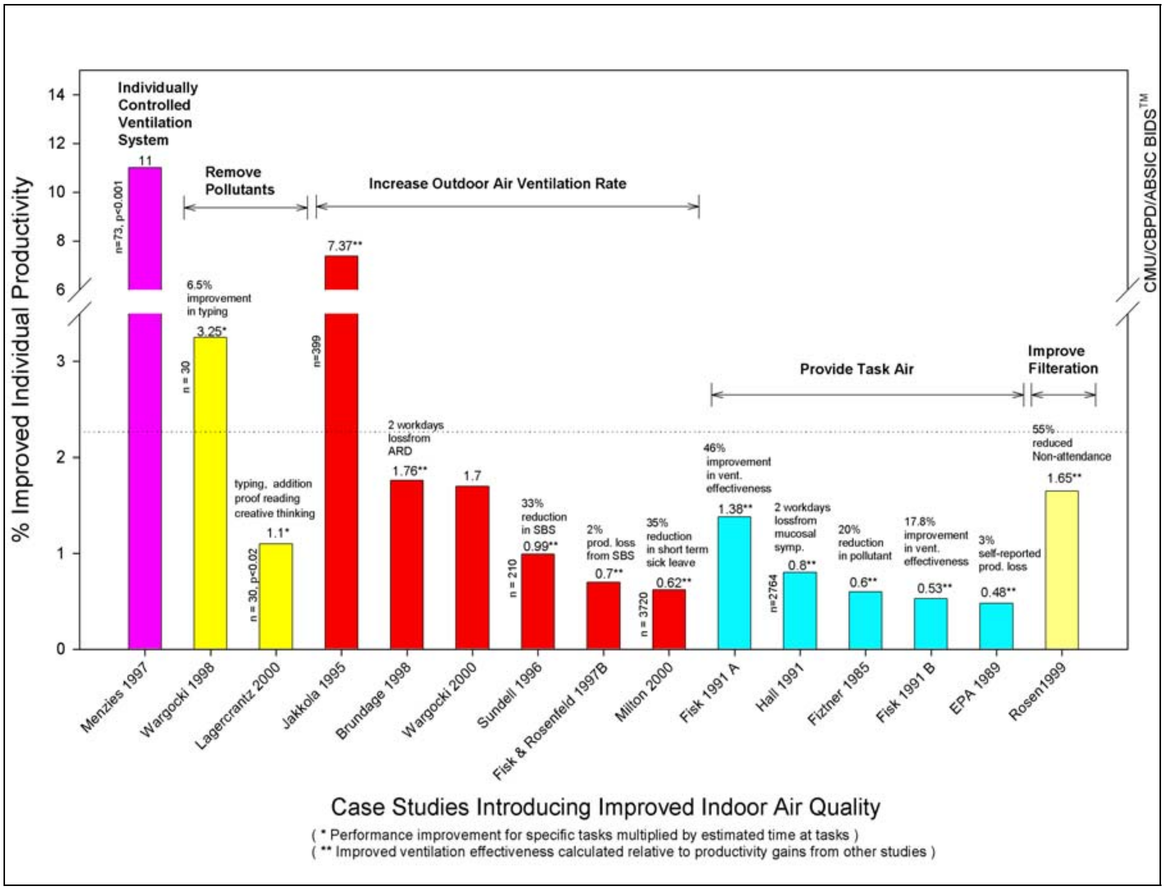

Figure VIII-4: Increased Temperature Control

The Center also looked at studies examining productivity impacts of worker control over temperature. As noted earlier, the BOMA/ULI study found that lack of control over temperature was one of only two features considered by respondents as both most important and of lowest tenant satisfaction. The mean productivity increase for temperature control in these seven studies is 1.2%.

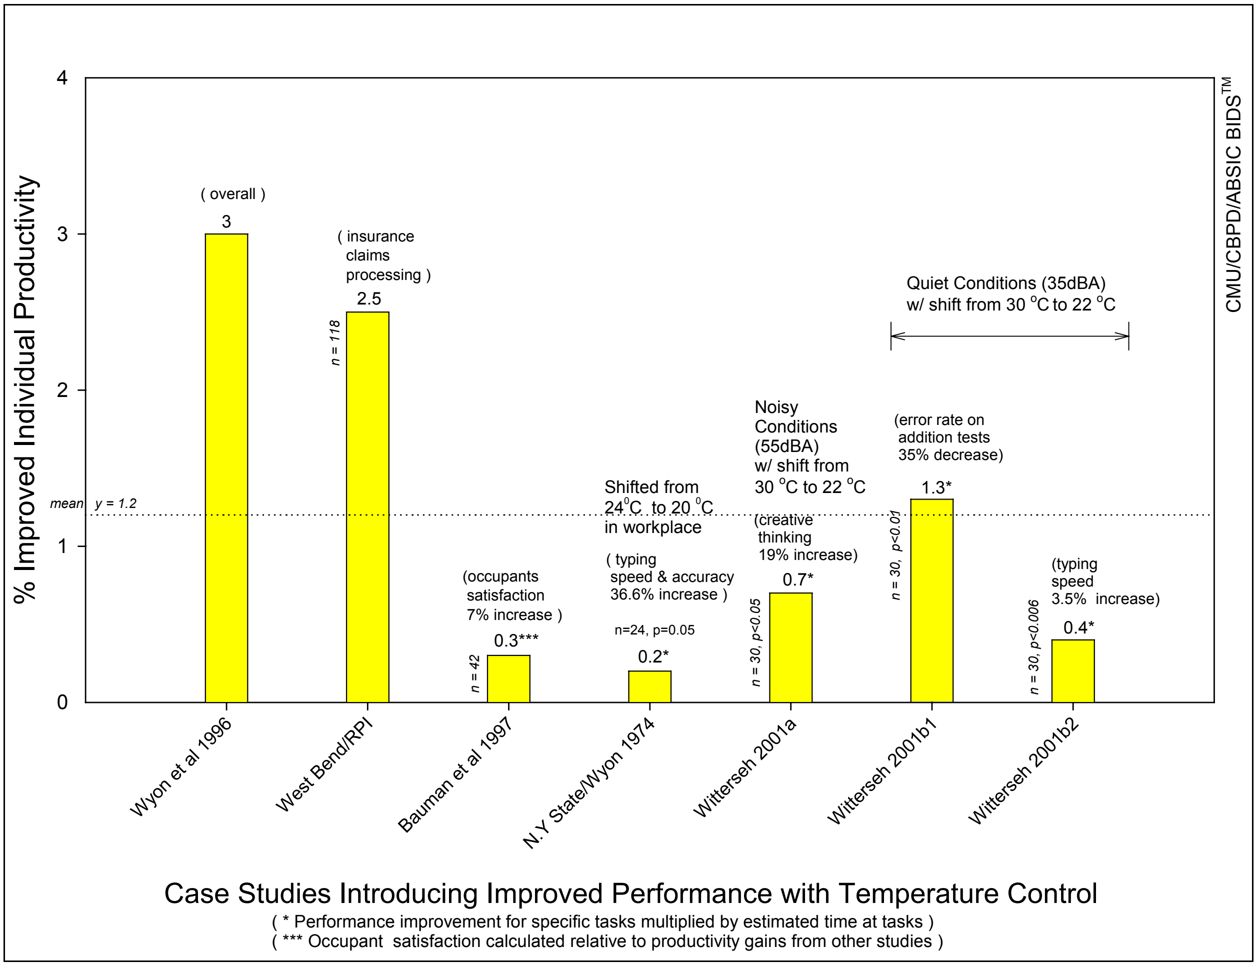

Figure VIII-5: Increased Lighting Control

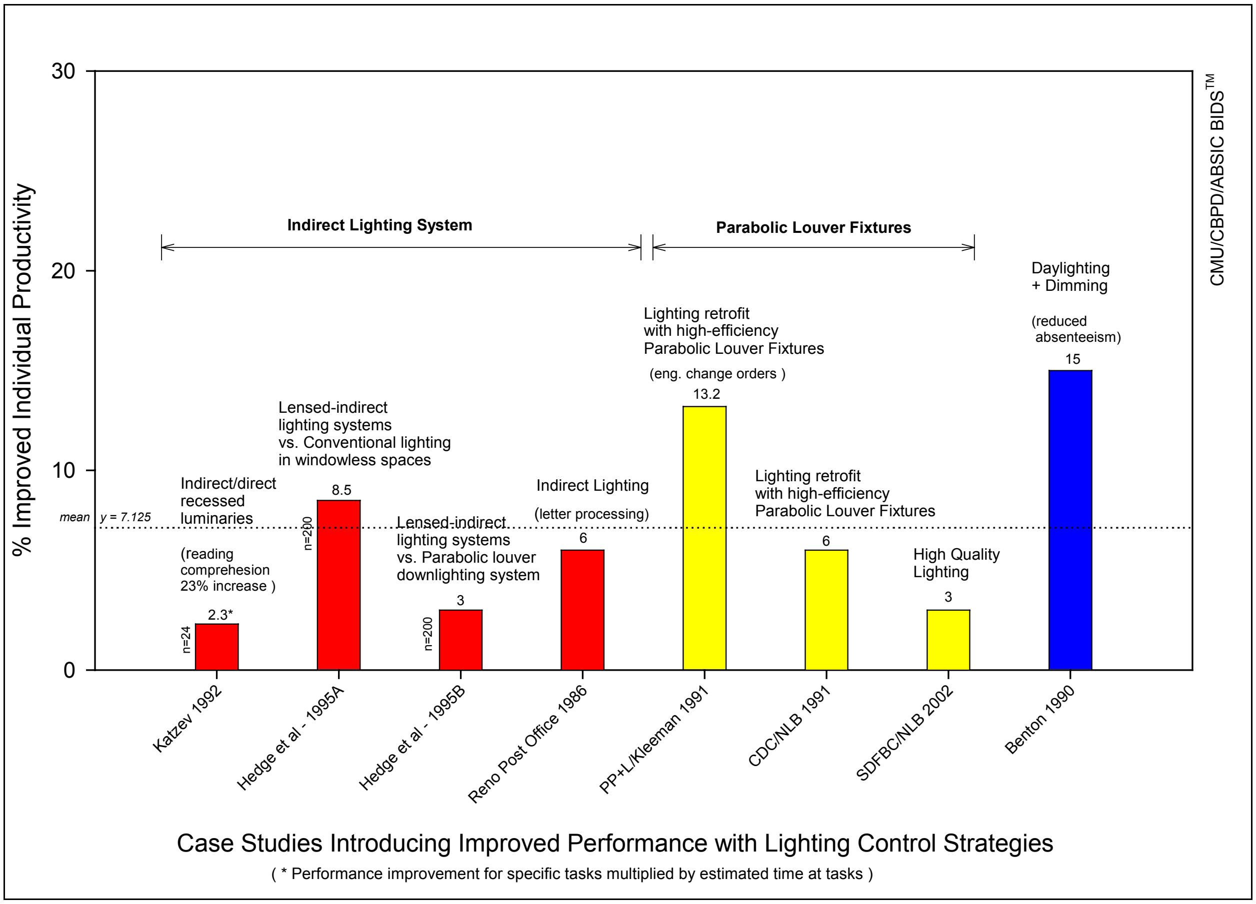
Eight studies measured the relationship between increased lighting control and productivity, finding productivity gains ranging from 3% up to 34%, with a mean of 7.1%.



Increased Daylighting

A study by the Heschong Mahone Group evaluated the test score performance of over 21,000 students in three school districts in San Juan Capistrano, CA; Seattle, WA; and Fort Collins, CO. The study found that in classrooms with the most daylighting, students' learning progressed 20% faster in math and 26% faster in reading than similar students in classrooms with the least daylighting. The overall findings show that increased daylighting and generally improving quality of lighting significantly improves student test performance.[243] The study's results have been widely quoted, although the large impact of daylighting quality surprised some people and raised questions about the technical thoroughness of the report. To ensure the study's validity, California's Public Interest Energy Research (PIER) program, administered by the CEC, funded a follow up study, employing an independent technical advisory group to reanalyze the data. The reanalysis confirmed the initial study's findings with a 99.9% confidence level.[244]

The kind of work done by "knowledge workers" – most state employees – is very similar to the work students do. Tasks include: reading comprehension, synthesis of information, writing, calculations, and communications. Large-scale studies correlating daylighting with student performance on standard tests therefore provide relevant insight about the impact of increased daylighting on state employees.

This study is important for its size, rigor and the large measured impact of lighting quality on standardized test performance. Note that the study compares performance between students with the greatest amount of daylighting and those with the least daylighting – two extremes. Therefore it is difficult to use this study to predict benefits of enhanced daylighting common in green buildings relative to conventional buildings. The productivity benefits that could conservatively be expected are much less than 26% (which reflects extremes in daylighting), perhaps on the order of 2% to 6%.

Sick Building Syndrome

Following (see text box, *The cost of sick building syndrome for California state and school employees,* below) are the results of an analysis of the cost of sick building syndrome (SBS) for California state and school employees.[245] It assumes a "conservative" 2% productivity decrease due to SBS symptoms. By comparison, a 2000 evaluation of three buildings with a total of over 600 occupants for the Portland Energy Office estimated a 1% increase in productivity and noted that this is "a very conservative estimate." [246] A National Energy Management Institute (NEMI) study entitled *Productivity and Indoor Environmental Quality*, estimates that productivity gains

[243] Heschong Mahone Group, "Daylighting in Schools: An Investigation into the Relationship Between Daylight and Human Performance," 1999. Available at: http://www.h-m-g.com; Follow up studies verified the rigor of analysis and subsequent research continues to show positive correlation between daylighting and student performance.

of 1.5% in "generally healthy" buildings are possible and even conservative.[247] As part of the state of California's Block 225 Capitol Area East End project, the Center for the Built Environment will be conducting a productivity analysis of workers related to indoor environmental quality efforts in that building. However, results from this study are not expected for approximately 2-3 years.[248]

The cost of sick building syndrome for California state and school employees
By Leon Alevantis, California Department of Health Services

SBS symptoms are most commonly reported by office and classroom workers. These workers make up about half of the state workforce. The impact of SBS to California office and classroom workers may be calculated as follows:

California office and classroom workers:

A telephone-based, state-wide survey of 14,729 adults (18 years or older) conducted in 1999 on behalf of the California Department of Health Services (DHS),[1] found that 54% of the adult population worked indoors. According to the 1999 California Current Population Survey, there were about 24 million adults living in California. Therefore, in 1999 there were about 13 million adults working indoors. Of those working indoors, according to the DHS survey, 54% or 7 million worked in an office or a classroom. This is about 44% of the annual average employment for 1999 (which was about 16 million).

SBS costs to California office and classroom workers:

Multiplying the number of California office and classroom workers by an annual average compensation of $43,000 (which was the annual average for these professions in 1998 according to data from the California Employment Development Department, excluding benefits and allocated O&M costs) and an estimated conservative decrease of 2% in productivity caused by SBS symptoms[2] the resulting cost of SBS symptoms to California is about $6 billion. Assuming that the average cost for benefits plus allocated O&M costs is an additional 50% of each worker's annual compensation, the resulting overall cost of SBS to California employers is about $9 billion.

Furthermore, published data indicate that 23% of office workers and teachers reported two or more frequent symptoms that improve when they leave their workplace. This implies that about 2 million California office workers and teachers are frequently affected by at least two SBS symptoms.

Conclusion

There is no standard for estimating the exact productivity impact of a green building. Each green building has a different set of technologies and design attributes, and each building population has different health attributes and comfort needs.

However, four of the attributes associated with green building design – increased ventilation control, increased temperature control, increased lighting control and increased daylighting – have been positively and significantly correlated with increased productivity. Additionally, there is a large range in potential productivity and health gains from improved indoor environmental quality summarized in Figure VIII-2.

There are also quantifiable green building gains in attracting and retaining a committed workforce – an aspect beyond the scope of this report. Attracting and retaining the best employees can be linked to the quality of benefits that workers receive, including the physical, environmental and technological workplace. Green buildings are designed to be healthier and more enjoyable working environments. Workplace qualities that improve the environment of knowledge workers may also reduce stress and lead to longer lives for multi-disciplinary teams.[249]

It is beneficial for the state of California to maximize health and productivity benefits across a large number of employees and a large number of buildings. The studies cited above indicate significant and measured productivity benefits across a large population of workers and multiple green buildings. Productivity impacts could be even greater in California schools, which often exhibit poor environmental health conditions and a lack of adequate maintenance (and associated maintenance budgets).[250] Therefore improvements in air quality in schools could have significant economic and human health benefits.

LEED rated buildings all address some combination of measures that help reduce the pollutants that cause sickness and increase health care costs; improve quality of lighting and increase use of daylighting; and increase tenant control and comfort. A review of LEED prerequisites and credits (see Appendix A) indicates that LEED is designed to specifically address the materials, designs and operations affecting productivity and health issues discussed above. Credits directly relating to productivity are included in the Indoor Environmental Quality section with two prerequisites and 15 credits (about 22% of total credits available). A preliminary review of green buildings submitted for USGBC certification confirms that these buildings consistently include a range of material, design and operation measures that directly improve human health and productivity. Gold and Platinum level LEED buildings are more comprehensive in applying IEQ-related measures and therefore should be viewed as providing larger productivity and health benefits than Certified or Silver level green buildings.

Calculation

Given the studies and data reviewed above, this report recommends attributing a 1% productivity and health gain to Certified and Silver level buildings and a 1.5% gain to Gold and Platinum level buildings. These percentages are at the low end of the range of productivity gains for each of the

[249] Communication with Vivian Loftness, CMU, February 2003.
[250] California Air Resources Board and California Department of Health Services. Draft Revised Report to the California Legislature: "Environmental Health Conditions in California's Portable Classrooms." 2003. Available at: http://www.arb.ca.gov/research/indoor/pcs/pcs.htm.

individual specific building measures – ventilation, thermal control, light control and daylighting – analyzed above. They are consistent with or well below the range of additional studies cited above.

For state of California employees, a 1% increase in productivity (equal to about 5 minutes per working day) is equal to $665 per employee per year, or $2.96/ft^2 per year.[251] A 1.5 % increase in productivity (or a little over 7 minutes each working day) is equal to $998 per year, or $4.44/ft^2 per year. At $4.44 per year, over 20 years and at a 5% discount rate (assuming that state employee salaries are unchanged with respect to inflation), the PV of the productivity benefits is about $36.89/ft^2 for Certified and Silver level buildings, and $55.33/ft^2 for Gold and Platinum level buildings. Assuming a longer building operational life, such as 30 or 40 years, would result in substantially larger benefits.

Note on Education [252]

LEED is broadly applicable to most commercial type buildings, and in most cases aspects of LEED will translate easily into other infrastructure areas. However, there are several issues that are specific to education buildings, particularly classrooms and laboratories. The US Environmental Protection Agency and the Department of Energy have collaborated to develop the Laboratories for the 21st Century or Labs21[253] program, which outlines a series of Environmental Performance Critera specific to laboratories. The USGBC is working with Labs21 in the hopes of developing a joint "LEED for Labs." K-12 classrooms also present a special case not specifically addressed by LEED.

California's Collaborative for High Performance Schools (CHPS)[254] has already had a substantial and very positive impact on California schools. For example, the Los Angeles Unified School District is one of five districts throughout the state that have adopted CHPS for all new K-12 school construction.[255] The CHPS program has developed a three volume Best Practices Manual outlining a range of green design technologies and practices.
